MORBID SOMNOLENCE AND ITS RELATION TO THE ENDOCRINE GLANDS.*

BY CHARLES L. DANA, M.D.,

NEW YORK.

PROFESSOR OF NERVOUS DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE.

SOMEWHAT over twenty years ago I wrote an article on "Morbid Drowsiness and Somnolence," of which the opening paragraph will answer now: "The earliest writer upon this subject was a physician of the first century, Aretaeus, who left two books upon 'The Lethargics.' Galen, who a little later covered the field of medicine for 1200 years, also made many references to abnormal somnolence and lethargy. On the other hand, at the present day we find that in the five large volumes on nervous diseases in Ziemssens' Encyclopædia there is barely a reference to this subject. Perhaps we are more wide-awake now than they were seventeen centuries ago."

The literature on the subject of morbid somnolence is still rather limited, but the subject has been more carefully defined and some of its causes successfully investigated.

Morbid somnolence and drowsiness is a condition which may occur as an intermittent phenomenon, or as a somewhat continuous performance, like that of the man whose case was recently reported in a German journal. He received a wound on the head and slept for three and a half years; he then recovered.

1. These cases of continuous sleep are usually cases of mental disease or of the so-called "hysterical" and "trance sleep."

2. Conditions of interrupted or prolonged somnolent states occur also in the depressive phases of manic-depressive insanity, and in dementia precox. They are also recognized now as being mental rather than sleep disturbances.

3. In certain rare instances something which resembles sleep attacks occur as equivalents for epileptic seizures, or hysterical seizures. These epileptic and hysterical sleep seizures include most of the cases which go under the name of "narcolepsy."

4. Perhaps the most familiar forms of seriously morbid drowsiness and somnolence occur as the result of senile or syphilitic changes in the circulation of the brain; or in severe exhaustion and autotoxemic states.

5. A good deal of attention has been paid to the somnolent and drowsy states that occur in organic disease of the brain, more specifically in tumors of the brain.

These are especially associated with tumors of

the third ventricle. Among 30 such cases collected by Weisenberg, drowsiness and somnolent tendencies occurred in six or 20 per cent., and in none of these was there any involvement of the pituitary gland. A conclusion has been drawn that pressure on the optic thalami blocks the sensory pathway and thus leads to somnolence and sleep.

All these types of somnolence are not particularly rare or puzzling.*

But there are other cases which are not so easily explained or are explained on the theory that they are due to disorder of ductless glands. It is to these that I wish to call attention now.

Ten years ago Salmon advanced the idea that physiological sleep was due to an internal secretion of the pituitary. A year later, Gemelli refuted this idea, and showed that in the hypophysis of the marmot during hibernation there was a decrease of secretory cells. Gemelli thought that the glandular hypophysis in connection with other ductless glands had the function of neutralizing toxins and had no especial relation to sleep.

Cushing was impressed with the fact that in hypopituitarism there occur phenomena much resembling those of hibernation, viz., unusual deposition of fat, lowering of blood pressure, pulse, and temperature, and oftentimes prolonged somnolence. He made a study of the subject in a series of hibernating woodchucks. He found that during the sleeping period there were changes in many of the ductless glands, the most notable occurring in the pituitary body. This gland diminishes in size and the cells of the anterior part lose their characteristic staining reactions. When hibernation ceases the gland swells and the cells increase again and acquire their affinity to differential stains.

He concludes on the basis of these observations that hibernation may be attributed to a physiological wave of endocrine gland inactivity, and he thinks that the essential rôle may be played by the pituitary body, since the most striking histological changes appeared in this structure, and since it has been shown that diminution of the secretion of this gland, and of this gland alone, produces symptoms comparable to those of hibernation.

This conclusion is plausible, though the phenomenon might be explained also in part on the theory that the glandular inactivity was the result rather than the cause of hibernation.

As illustrating the influence of tumors of the

*Going over now a list of twelve personal cases of marked somnolence and drowsiness, I find I can explain them as being due in one case to epilepsy; in two cases to arteriosclerosis and autotoxemia from overindulgence in food and alcohol; in two cases to profound fatigue from excessive work with cardiovascular weakness and very low blood pressure; in four cases to the depression of melancholia; in three to abnormal constitutional conditions, defect of habit—the patients were born with sleep defects, but with no mental or physical defects; in two to dementing conditions.

*Read at a meeting of the Practitioners' Society, Nov. 5, 1915.

pituitary in producing somnolence, he cites the case of a man of forty-eight with an interpeduncular tumor, involving the pituitary gland. There were characteristic morbid pressure symptoms, but in addition there were evidences of hypophyseal insufficiency, and among these symptoms was drowsiness which became one of the leading symptoms. The patient not only passed most of his day in slumber, but on a number of occasions he slept for several days. And once he slept so deeply and there was such a marked slowing of respiration that artificial means were resorted to for its continuance. His somnolent symptoms were improved by subcutaneous injections of the anterior lobe extract and by sellar decompression, and finally and markedly by the implantation into the subcortex of the brain of the pituitary gland of a stillborn child. This also produced an astonishing improvement, but in one or two months he relapsed and died.

The Endocrine Glands.—The three major ductless glands are the suprarenals, the thyroid, and the pituitary, these being especially characterized by the fact that they each have two kinds of tissue.

The minor glands are numerous and perhaps not yet altogether known. They would include the thymus, the interstitial cells of the gonads, the islets of Langerhans, certain duodenal glands, the corpora lutea, the uterine and mammary glands, the placenta, the pineal gland, and perhaps the liver.

With regard to the first three, the major glands, there are rather definite clinical conditions associated with decrease or increase in their activity. We have hypo- and hyper-thyroidism. We have hypo- and hyper-adrenal condition, and we have hypo- and hyper-pituitary conditions. With regard to the suprarenals and the minor endocrine glands, there are certain pathological conditions associated with them, but in none of these except perhaps the pineal* does there occur anything that suggests a disturbance of sleep.

In conditions of marked hypothyroidism which have developed into myxedema there is a mental apathy and stupor, but there are no characteristic periodic sleep attacks and no condition which resembles prolonged somnolence. One does see, however, conditions of hypothyroidism in which apathetic tendencies and sluggish mind conditions are improved very much by thyroid extract; so that it seems possible that thyroid deficiency may be one factor in the production of morbid somnolence.

The facts regarding the pituitary gland are much more definite. In affections of the anterior part when leading to acromegaly there is sometimes a certain amount of mental dullness and apathy, and there are sometimes also somnolent seizures.

In affections of the posterior part with probable deficient functioning there occur along with adiposity, genital atrophy, slowness of respiration and pulse, low blood pressure, low temperature, a great tolerance of carbohydrates, distinct periods of drowsiness and sleep; so that this condition is sometimes a characteristic feature of that group of symptoms known as the "Fröhlich syndrome."

As an illustration of this are various cases of dyspituitarism, of which the following summary of a history kindly furnished me by Dr. Walter L.

*Hypopinealism is characterized (Frankl-Hocht) by abnormal pituitary structure; excessive growth; hair; obesity; premature genital and sexual development; precocious adolescence; drowsiness.

Niles is a case in point (The case is reported in full in this issue):

CASE I.—*Summary:* Male, age 23, normal mentally and physically and of slender build until four years ago. Then his eyesight began to fail. He grew fat and sleepy, occasionally a frontal headache. Visceral, renal, cardiovascular conditions and blood normal. Figure of feminine type, tapering fingers. Marked deposits of fat, genitals small. Thyroid not enlarged. Much suprapubic hair, skin rough, and dry. Hair of head, face, and axilla normal. No pigmentation. Temperature constantly subnormal. Pulse 90 to 100. No enlargement of sella turcica. During the day he is very drowsy, sleeping in his chair, and even while standing up. Some mental deterioration. Marked polyuria, an abnormal tolerance to carbohydrates. (Fig. 1.)

Dr. William M. Leszynsky recently reported a case of a somewhat similar type.

CASE II.—*Summary:* A boy of 17, normal until his

Fig. 1.—Dr. Niles' Case of Morbid Somnolence and Hypopituitarism. (See also Figs. 3 and 4 on p. 7.)

twelfth year, when he began to increase in weight and had severe headaches. In his sixteenth year he began to lose his eyesight and in six months his right eye became blind; he had difficulty in walking, had attacks of vertigo. He began to get dull, stupid, and somnolent. He slept from twelve to fourteen hours daily and fell asleep at inopportune times. He had when examined pronounced adiposity (weight 152 pounds, height four feet nine inches) and a feminine type. Skin was dry, no hair in axilla and little on pubis, genitals undeveloped, fingers tapering. Mentally retarded. Sella turcica not enlarged, but base was irregular in outline. Nystagmus and primary optic atrophy.

Dr. Kraus, in the *American Journal of the Medical Sciences*, has reported a case of an irregular form of the Fröhlich syndrome under the title "Pilous Cerebral Adiposity."

CASE III.—*Summary:* The patient was a man, aged thirty-one, who had a fall on the head at the age of four, followed by Jacksonian epilepsy which lasted from

the age of thirteen to the age of twenty-six. Then the Jacksonian epilepsy ceased and he became obese, hairy, and sleepy. His weight increased to 282 pounds, and there was great development of hair over the body. He developed attacks of profuse sweating. He had a carbohydrate tolerance of 700 grams. There was geni-

Fig. 2.—Dr. Kraus' case of pituitary cerebral adiposity with somnolence.

tal atrophy and he began to suffer from drowsiness and somnolence during the day, and excessive prolongation of the normal hours of sleep. He was intelligent and jolly and had no signs of a brain tumor; no changes in the cranial nerves; no change in the shape of the sella turcica. (Fig. 2.)

However, the Fröhlich syndrome is not always associated with somnolence:

CASE IV.—Last winter I had in my clinic and under charge at the Neurological Institute a boy aged twelve, who had within the previous two or three months been developing symptoms of intracranial pressure, viz., headache, vomiting, and papilloedema. Examination showed him also to have developed the adiposity and genital atrophy such as characterize in the Fröhlich syndrome. Superimposed on this came symptoms of a brain tumor. His most serious condition was the choked disc, with impaired vision. Dr. Elsberg performed a callosal puncture on him and this showed that the fluid in the ventricles was under very high tension. After the operation the headache and vomiting disappeared and the general condition was improved, but the eyesight was too far gone and the boy became blind.

Mentally, he was unusually bright and alert and never drowsy or somnolent. (Fig. 3.)

The foregoing cases and evidence submitted are sufficient to show that pituitary disease has something to do with certain cases of morbid somnolence and that it may produce morbid somnolence without any of the "neighborhood symptoms" due to brain disease or to tumor invading the third ventricle. The question then presented itself whether certain obscure cases of morbid somnolence might not be explained on the basis of some functional disturbance of this gland.

In illustration I submit the two following histories:

CASE V.—Morbid somnolence, doubtful hypophyseal disease. Mr. A. McC., aged 30, single, carpenter. The family history is negative. Personal history: The patient was born and grew normally. When he was five years old, he fell from the second-story window

and received a severe head injury. A year later, when he was six years old, he began to have attacks of drowsiness and sleep seizures. He would sleep late in the morning and when going to school he would fall asleep at his desk; so that he was not able to keep in his classes, and failed to get an adequate education. As he grew older, the condition of drowsiness and the somnolent attacks increased.

When I saw him first, he was at the age of twenty. He was then trying to make a living as an insurance collector, but his sleep habit soon lost him this job. He would fall asleep when he was walking in the street and would continue to walk in a straight line until he ran into something that woke him up. He would go to sleep also while at his meals, and he would fall asleep while carrying food to his mouth.

During this condition of sleep his face did not change color, except for a slight red spot which appeared on each cheek—a kind of flush. He never had made any spasmodic movements. He would go to bed at about 10 and sleep until 8 the next morning, and on some days until 10, 11, or even the whole of the next day. When he awoke he was quite ready to go to sleep again. When I first saw him he had already lost four positions because he went to sleep at his work. He took, for example, a position in a designer's office and was given a model. He took this and put it in front of him and then went to sleep.

In October, 1915, I saw the patient again, after a lapse of ten years. He stated then that he was considerably improved, and was able to keep awake with some effort during the day. If, however, he followed inclination he would go to sleep at his work.

When he gets home and sits down to rest he falls asleep. He does not fall asleep over his meals and during the night he sleeps about nine hours. He says that he feels better, but still has some headaches, has to fight sleepiness, and has had one or two attacks of dizziness. He also has attacks of leg weakness, in which his knees tend to give way and he has to make an effort to prevent himself from falling.

He has always a good deal of trouble with his nose, which was originally broken. Nine years ago he spent two weeks in the Manhattan Eye and Ear Hospital having his septum adjusted and his posterior nasal fossa cleaned out. He still has some difficulty in nose breathing and has one quite enlarged tonsil. Otherwise

Fig. 3.—Fröhlich Syndrome. Brain (Pituitary?) Tumor with Unusual Mental Alertness and No Somnolence

the patient's health is good. He is mentally alert and a man of considerable intelligence. The physical examination at this time shows the following: The patient is below the average height, 5 ft. 4½ in. His weight is normal, 136 pounds. As a boy he was plump but never fat. His head is large and might be termed

"hexagonal" or square shaped. He wears a 7 $\frac{3}{8}$ hat. His feet and hands are rather large, but not abnormal. His fingers are rather squat, not pointed. He is not round shouldered, but stands fairly straight. His skin is smooth, not dry, and indeed he perspires rather abnormally. He has freckles over the shoulders and arms from exposure to the sun. The face is not characteristic of dyspituitarism. It is rather suggestive of a chronic hydrocephalus, if anything, the brows being rather prominent and the facial bones rather small. The teeth and jaws are normal; no wrinkling of the forehead. The hair on the head is thick and does not grow low. He is smooth shaven, but could grow a beard. The hair on the body is scanty but not abnormally so, and is abundant on the pubes and in the axilla. There is no excess of subcutaneous fat nor of breast tissues. The figure is a masculine type. The thyroid is palpable. Thoracic organs, normal. Pulse, regular and 80. Temperature under the tongue, 97.8°. Neurological status: The gait and station are normal. The hands show no tremor. Cranial nerves: The vision is very hypermetropic, but when corrected is normal. No limitation of the visual fields. Slight nystagmus on lateral fixation. Ocular movements otherwise normal. Pupillary reflexes, normal. Pupils, even. No facial

Fig. 1. Roentgen Ray Photograph of Skull of A. McC. (Taken by Dr. A. P. Evans), Showing the Sella Turcica.

tremor; no tremor of the tongue. Hearing and equilibrium sense, normal.

It is already stated that the patient has had adenoids and tonsils removed, and the deviated and broken septum straightened. But he has always had, in spite of that, much catarrhal trouble, probably sinusitis and rhinitis and hypertrophied tissues in the back of the nose and throat.

He used to have migrainous headaches, but now he has catarrhal headaches about every week. The urine is normal. The blood count was not taken. Examination by x-ray showed: Absence of anterior clinical processes and a shallow sella. Dr. A. P. Evans, who made the plate, writes: "The sella turcica appears as a very shallow depression. The posterior clinoid processes are present, but there is no shadow corresponding to the anterior clinoid processes. This sella turcica must be considered as enlarged, although there is no erosion of the body of the sphenoid. The frontal sinuses are very large and double. The antra and sphenoidal sinuses are clear."

The evidence in favor of this case being a form of somnolence due to pituitary gland trouble is not very strong, and yet it has certain weight. There is:

First, the history of a severe fall and injury to the head preceding the attacks of somnolence. There could have been easily some injury to the pituitary gland through the result of such a fall at that time. Second, there is the evidence of a slight hydrocephalus in the enlarged and square-shaped head. Chronic hydrocephalus leads sometimes to pituitary diseases.

Third, there is the fact of a rather low temperature.

Fourth, there is a history of a great deal of nasal and post-nasal trouble, and it is not difficult to imagine that some functional pituitary disturbance might have been caused through this catarrhal and inflamed condition. I have two other patients who suffered from persistent somnolence and who had long standing post-nasal disease.

Fifth, the x-ray shows some defect of the sella turcica.

Sixth, improvement under pituitary feeding.

CASE VII.—H. G. C., male, aged 41, married; no children; artist by occupation. The family history is negative.

The patient has been a strong man, a very hearty eater, and of rather lazy disposition. His habits have been good. He has had no infection, and he has not been excessive in the use of alcohol or tobacco. About a year ago he began to get sleepy. He would go to bed at nine o'clock and sleep until eight in the morning. He would then get up and eat his breakfast, and then go to sleep again and sleep all day, unless he was urged to keep at some active work.

While he is on his feet and walking about and doing something he can keep awake. If he is kept awake in the forenoon by active work he will eat his lunch and perhaps paint for an hour and then sleep until supper time. Then go to bed and sleep eleven hours.

His sleep is very heavy and deep. He snores noisily and can be awakened with difficulty. He goes to sleep sometimes when he is at table or at the toilet or while sitting on a chair. Sometimes he goes to sleep and sleeps so heavily that he falls off the chair on the floor and has recently hurt himself by such a fall. His somnolence is not accompanied with any twitchings, and he has no fainting turns or aura or any suggestions of epilepsy or convulsive disorder.

His mental condition is apparently normal when he is awake. He has no defect of memory. His powers of comprehension and narration and judgment are apparently as good as ever.

Examination shows him to be a rather fleshy man, weighing 224 pounds, height 5 feet 11 inches with large head. His gait and station are normal. His physiognomy shows a considerable deposit of fat and rather large mammary glands, but no feminine shape to his body; no excess of hair. Skin is not especially dry or moist.

His cranial nerves are normal; his sight and field of vision are normal. He has no nystagmus and no evidence of visual trouble. No optic nerve involvement. His reflexes are normal and he has good control of his hands, being able still to paint.

His heart is normal; pulse rather fast; blood pressure 104.

He has had his skull x-rayed and it shows no abnormality of the sella turcica. There is no change in the shape of his hands or skull bones and the skin is normal in feel.

He has been treated by Dr. Wilson of 616 Madison Avenue, on the theory of dyspituitarism, and he has been given, as I understand, pituitary gland without any effect.

The results of the laboratory examinations are as follows. There is a slight degree of anemia, endocrine blood change, some excess of indican in the urine which is rather concentrated. The gastric acidity is below par. The phenolphthalein test of the kidney is normal. I had no tests made of the nitrogen of the blood.

Dr. Wilson was kind enough to send me his report of the examination of the urine for excretion of levulose. These tests indicate that there was no insufficiency and that the levulose was handled in a normal way. Dr. Wilson's examination of the urine also indicated a high specific gravity and excess of

acidity and a very decided excess of indican, otherwise it was normal. His examination also showed some slight grade of anemia with some excess of white blood cells, but no trypanosoma.

The examination of the stools showed no evidence of hookworm or other parasites.

The most marked symptoms are: Somnolence, obesity, condensed urine, indican, endocrine blood changes, low blood pressure.

It is difficult to assign the cause of this somnolence, but it seems easiest to explain on the basis of autotoxemia and ductless gland disorder.

We find that morbid drowsiness and somnolence occur in connection with:

1. Anterior lobe disturbance, as in acromegaly.
2. Posterior lobe deficiency as in the Fröhlich syndrome. We find that such somnolent conditions may occur when there is no other lesion such as neighborhood tumors or hydrocephalus.
3. Morbid drowsiness and somnolence occur, however, also in cases of tumors of the neighborhood region, whether these tumors involve distinctly the hypophysis or not.
4. Also in cases of other central brain disorders, such as chronic hydrocephalus and perhaps in pineal gland disease.
5. There are obscure cases of drowsiness and somnolence occurring in persons who have no distinct evidence of organic brain disease, but who have some of the minor symptoms of dyspituitarism. Hence, in these obscure cases investigation should be made for hypophyseal defects. These symptoms are liable to escape notice unless hunted for. They are sella changes, adiposity, hyper- or hypotrichosis, genital atrophy, impotence, amenorrhea, carbohydrate tolerance, endocrine blood changes characterized by an increased number of white blood cells, diminution in polynuclears and a mononucleosis or increase in the number of lymphocytes, and the absence or presence of a large number of eosinophiles.

In addition, there are the symptoms of low blood pressure, slow pulse and dryness or perhaps excessive wetness of the skin.

In hunting for such groups of symptoms, it must be borne in mind that there may be pluriglandular disturbance and that the thyroid, the pineal gland, and perhaps the suprarenal glands must be investigated.

Finally, one can say that there is no glandular organ whose disturbed function is so often associated with marked drowsiness and somnolence as the pituitary (15 per cent. to 20 per cent. of ordinary cases), and such somnolence can occur in cases in which the gland disorder is not associated with symptoms of neighborhood tumor invasion or general brain pressure.

The somnolence of hypophyseal disorders is especially due to deficient action of the posterior lobe associated with some disturbed functioning of the anterior lobe.

So that morbid somnolence, so far as it is hypophyseal, is probably due to defective action of the whole gland.

Sleep is a biological phenomenon which needs to be explained only as the waking state, or the diastole and systole of the heart need to be explained. It is not forced upon the system by any special hypnotizing secretion. It is part of the inherent and rhythmic habit of living tissue.

In sleep there is a blocking of the sensory inflow and of many association paths. Hence we might expect drowsiness from pressure on great sensory stations like the optic thalami.

This nerve block is caused ordinarily and in part by fatigue products acting on the synapses of the neurons. The activity of such product is perhaps antagonized by the pituitary secretion (Gemelli).

If this pituitary secretion is lessened as in disease the blocking action of fatigue products is greater and morbid somnolence occurs.

With or without such a hypothesis, we are justified in paying closer attention to the endocrine glands in their relation to morbid somnolence.

DYSPITUITARISM, PARTICULARLY OF THE POSTERIOR LOBE.

By WALTER L. NILES, M.D.,

NEW YORK.

ASSISTANT PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE; ASSISTANT ATTENDING PHYSICIAN TO BELLEVUE HOSPITAL.

ALL recent studies of the pituitary body tend to substantiate the conclusion of Cushing, that it is a dualistic organ, both anatomically and functionally. The anterior lobe influences, if it does not control, skeletal development, while the posterior lobe is related to the processes of metabolism, especially the assimilation of carbohydrates. Experiments and clinical observations justify the assumption that functional hyperplasia of the *pars anterior* results in gigantism if it exists prior to completion of epiphyseal union, while such hyperactivity subsequent to epiphyseal union produces acromegaly; hyposecretion retards skeletal growth and may result in infantilism. Insufficiency of the secretion of the *pars posterior* leads to adiposity with increase in tolerance for carbohydrates, while an excessive secretion causes wasting of the tissues with relative intolerance for carbohydrates.

These functional disturbances may result from tumors of the hypophysis, or pressure upon it from adjacent growths, hydrocephalus, or increased intracranial pressure from any cause, and they may possibly occur without any gross change whatever. As the secretion from the posterior lobe reaches the blood stream by way of the cerebrospinal fluid, stasis of this secretion may result in changes similar to hypoplasia of the gland.

Most examples of dyspituitarism give evidence of more or less disorder of both lobes, but usually with predominant symptoms referable to one of them. The syndrome of dystrophia adiposogenitalis (Fröhlich's syndrome) apparently is the outcome of chronic inactivity of both anterior and posterior lobes.

Since the publication in the *American Journal of the Medical Sciences*, cxlv. 3, of Cushing's paper on the symptomatic differentiation between disorders of the two lobes of the pituitary body I have studied two cases of posterior lobe hypopituitarism, both of which showed little evidence of disturbance of the anterior lobe or of other endocrine glands.

CASE I.—A boy, aged 13 years, came under my observation on April 19, 1913. He is the elder of two children; birth was difficult and his head was misshapen for some days following, though forceps were not used. The boy's mother, and all of her family tend to obesity, but none were fat in early life. His weight at birth was 8½ pounds; at three months, 13½ pounds; at six months, 18 pounds; at nine months, 27½ pounds. He has always been fat, but during the previous year the increase has been especially noticeable, though he has gained little in height. Upon two occasions he has fainted, following slight injuries, and during one attack his face twitched. The attending physician subsequently told his father that it was suspicious of epilepsy.

His appetite is enormous, especially for carbohydrates. He wears heavy clothes and in the summer requires heavy bedding. He is not unduly sleepy, nor does he have headache. He is emotional and cries on slight provocation, but is an attractive boy with a charming personality, his intelligence being quite up to the average.

In the summer of 1911, he is said to have stepped in a rabbit hole, following which he had pain in his right hip and limped. This did not improve until a cast was applied in June, 1912. Following its removal in August, 1912, he had little pain or disability until March, 1913, when it became worse than at any previous time.

Physical Examination. A bright, active, fat boy,

weighing 150 pounds (normal average 88.3 pounds), and measuring 63.5 inches in height (normal average 58.2 inches. His conformation is distinctly feminine, broad hips and thighs with tapering extremities, the hands and feet small. There are heavy pads of fat over the abdomen and mammary regions. The skull is

FIG. 1. Case I. Excessive adiposity and rarefaction of the surgical neck of the right femur.

not large (55.5 cm. in circumference). Neuromuscular and other systems are negative. He has polyuria, passing 65 to 80 ounces of urine daily, which is of low specific gravity, but otherwise negative. Blood, negative.

The skin is rather coarse and dry. The hair of the scalp is thick and brittle; there is no hair elsewhere. The genitalia are noticeably small and under-developed. The temperature is markedly subnormal, being 96° in the morning and only once in three weeks did it reach 98° in the evening. The pulse is uniformly 80 to 84. Blood pressure, 125 systolic, 80 diastolic.

During a five-day period without dietary restriction he averaged 35.2 calories per kilo, but his parents said he ate much less than usual, and a loss of 3 pounds in weight confirmed it. Feeding 200 grams of levulose did not produce glycosuria, but did result in urticaria which prevented further tests of carbohydrate tolerance.

FIG. 2. Case I. Radiogram of skull, showing an exceedingly small sella turcica and sphenoid bone.

A radiogram of the cranium shows a very small sella turcica on a non-cellular, solid sphenoidal base.* Many radiograms of the hip were made and showed an abnormal appearance of the surgical neck of the femur

*Dr. E. W. Caldwell says the sella turcica is one of the smallest he has ever seen.

which was difficult to interpret. There was distinct rarefaction and some irregularity in the outline which did not appear to be in the periosteum. Several observers thought the condition was tuberculous, but Dr. Virgil P. Gibney, under whose orthopedic care the boy was placed, insisted that it was not, and this opinion

FIG. 3.—Case II. Obesity, narcolepsy, and cerebrospinal syphilis, with bilateral optic atrophy. (See also Fig. 1 on p. 2.)

was concurred in by Dr. E. G. Brackett of Boston. There was subsequently increased angulation of the surgical neck of the femur, so that the leg became shortened three-fourths of an inch. Other bones were normal.

The results of treatment have been very interesting and satisfactory. His food intake was reduced to about twenty-four calories per kilo per diem, and he was given 1/10 gr. posterior lobe of pituitary gland three times daily by mouth. Perhaps the most striking change was in the temperature which at once began to range between 98° and 99.4°. This continued for eighteen days when it began to sag and again became 96° to 97°. The amount of pituitary extract was doubled and it immediately became quite normal, never being noted below 98°. This continued for two months, when the gland was stopped, and four days later the temperature dropped about 1°, again to become normal upon resuming the extract. After four months of treatment, his weight was 114 pounds (a loss of 36 pounds), the temperature was normal and his urinary excretion averaged 35 ounces. While he had heretofore not been regarded lethargic, everybody noticed that now he was far more active both physically and mentally, and during the next year stood at the top of his class in a large school.

During most of the first year of observation, the right hip was kept in a cast, which of course interfered with his enjoying much exercise. It was subsequently massaged and given passive and active movements, and now appears to be perfectly normal, except for the angulation of the surgical neck of the femur and consequent shortening of the leg. He weighs 145 pounds at present, but carelessness in overeating results in rather rapid gain in weight. His genitalia appear normal, and the pubic hair is profuse, though rather feminine in distribution.

Feeding of the pituitary extract was continued for six months, after which calcium lactate and thyroid

extract were given for about the same length of time.

CASE II.—Herman M., aged twenty-three years, single, was admitted to the Second (Cornell) Medical Division of Bellevue Hospital on February 27, 1914, complaining of weakness, obesity and impaired sight. His father, mother, five sisters and one brother are living and well without a history of any similar trouble. He has never been sick excepting measles at four years of age. As a child he was sometimes "foolish" but not stupid. He was thin and slender until nineteen years old. He has worked as a machine operator on clothing, earning \$7 per week until Christmas, 1913. His habits are good and a history of venereal infection is not elicited.

Present Illness.—Four years before admission, he began to get fat, and his vision to fail. He drank large quantities of water and urinated often. Frontal headache was occasionally mentioned, but it was never severe. He became very sleepy, especially in the day time, but at night he slept little. He eats great quantities of food, especially carbohydrates. He has had no nausea or fits, nor has he been paralyzed, though he is weak. He feels the cold greatly and requires more blankets than anyone in the ward. So far as is known, he has never exhibited any sexual desire.

Physical Examination.—A light complexioned, fat, good natured young man. Height, 66 inches. Cardiovascular, renal and other systems negative. Blood pressure, 135 systolic, 90 diastolic. Blood, normal. Temperature is constantly subnormal, ranging from 97° to 98°. Pulse, 90 to 100. Eyes: no muscular deficiencies; there is partial optic-atrophy about equal in both eyes. There are no scotomata for color or form (Dr. R. G. Reese). The skeletal configuration is feminine with broad hips and tapering extremities, especially the fingers, and there are large deposits of fat about the clavicular, mammary and pelvic regions. The skin is rough, harsh, dry, and he never perspires. There is no pigmentation. He has a good crop of hair on the head, axillæ and face. The suprapubic hair is widely distributed. The thyroid is not enlarged. The penis is small and the testicles are small and soft.

All extremities are weak and there is a fine tremor of the hands. Superficial reflexes, normal. No palsies. Knee jerks are exaggerated and equal. Ankle jerks, also over-active. No clonus or Babinski. The tongue is deeply fissured and covered with small, superficial erosions. Radiograms of the skull show the sella turcica to be normal in size; the sphenoidal base is dense (non-cellular). There is no evidence of increased intracranial pressure. Blood Wassermann, weakly positive. Spinal fluid: Wassermann positive, fourteen lymphocytes per cmm.

A note by Dr. E. F. DuBois on April 1, 1914, is as follows: "He has been restless and so stupid that it has been necessary to keep him in bed to get twenty-four hour specimens of urine. He gets up every few minutes at night and wanders about the ward. During the day he is very drowsy, sleeping in the chair or even when standing up as has frequently been observed. He is good natured, rather slow of speech and apparently understands even his own language (Yiddish) with

FIG. 4.—Case II. Photograph taken, with sisters seven years before the time Fig. 3 was taken. Note acromegalic features of sisters.

difficulty. He forgets instructions quickly and weeps when his breakfast is withheld but soon forgets his troubles. His voice has a peculiar, harsh, monotonous, nasal quality. He has a marked polyuria passing four to five liters daily."

The first time in the calorimeter, fourteen hours after

his last meal, his metabolism was 21 per cent above normal. After 200 grams of dextrose it was only 2 per cent above normal and there was no glycosuria. During 25 days, most of the time on regular diet, he gained seven pounds (155 to 162).

He was given neosalvarsan, mercury, and iodides but without improvement. During a seven-day period when he received 2/10 gr. extract of the posterior lobe of the pituitary gland three times daily, and was subjected to a moderate restriction in his diet his temperature rose to 99.5° and he lost five pounds in weight. Attempts at dietetic control resulted in his becoming dissatisfied, however, and his parents took him home.

I was fortunate in securing a photograph taken with two sisters when he was sixteen years old. He appears to have been quite normal, but his sisters, one of them especially, show acromegalic features. His parents were normal.

Case I is of interest because the dyspituitarism began before puberty and was accompanied by changes in one bone (the neck of the femur) which resulted in permanent deformity. Whether this was the result of hypopituitarism is problematical; it, however, differed from any familiar condition and, considering the rarity of both affections, the chances are in favor of their association with each other. The only evidence of anterior lobe disturbance is his rather large skeleton, but without the usual features of acromegaly.

Case II showed all of the known symptoms of posterior lobe hyposecretion without any evidence of disturbance in the anterior lobe or other ductless glands. He certainly had cerebrospinal syphilis but without definite indication of a tumor in any part. It seems possible that syphilitic changes had developed in his pituitary gland.

The positive results which are obtained from feeding extract of the posterior lobe of the pituitary gland add to the importance of differentiating disorders of the various ductless glands from each other and recognizing the various types of dyspituitarism, which can now be done.

56 EAST SEVENTY-SEVENTH STREET

SPASMODIC STRICTURE WITH DILATATION OF THE LOWER ESOPHAGUS.*

By THOMAS WRAY GRAYSON, A.M., M.D.,
PITTSBURGH, PA.

HAVING three cases of dilatation of the esophagus to report, I wish in the following article to give an outline of this condition, a description of one method of treatment, then an account of three cases, and lastly a discussion of these cases in the treatment of which I have learned a few points worth reporting.

Organic strictures may exist in any part of the esophagus and be caused by different conditions (burns, cancers, aneurysms, etc.). Naturally the resulting diverticula or dilatations may exist in any part of the gullet; but this article deals only with those dilatations of the lower esophagus which apparently are the result of spasm of more or less obscure etiology.

Many names have been applied to this condition such as "cardiospasm," "phrenospasm," "abdominal esophagismus," "hiatal esophagismus," "cardiospasm with successive dilatation," "spindle-shaped dilatation of the esophagus without anatomical stenosis," "congenital dilatation of the esophagus," "idiopathic dilatation of the esophagus," "spasmodic diffuse esophagus dilatation," "paralytic dilatation of the esophagus," etc.

*Read before the College of Physicians, Nov. 11, 1915.

Chevalier Jackson says (*Laryngoscope*, July, 1913), "The word *cardia* is properly used as the name of the esophageal orifice of the stomach. Spasm limited solely to this orifice is certainly exceedingly rare; while spasms of the abdominal

FIG. 1.—Sketch showing how the normal esophagus passes through the diaphragm and merges into the stomach.

esophagus and of the esophagus at the hiatus, either separately or together, are relatively common and should be called by their proper names, and the word "cardiospasm" should either be dropped as a misnomer or limited to those rare cases of true "cardial esophagismus." (See Fig. 1.)

The lower end of the esophagus passes through the diaphragm; then the abdominal esophagus from the diaphragm to the cardia is about 2 to 4 or 5 cm.

FIG. 2.—Sketch showing where the dilatation of the esophagus usually occurs.

long before it merges into the stomach. It is well established that there is no sphincter at the cardiac end of the stomach, that the muscle fibers there are not more numerous nor differently arranged than in the adjoining portions of the esophagus and stomach. For this reason the best known name for this complaint, "cardiospasm," is a misnomer. While there may be a spasmodic condition of any segment of the esophageal wall, the usual cause in these cases is not a spasm at the cardiac opening (where there is no sphincter muscle) but a spasm of the diaphragm or of the esophagus at or below the diaphragm. (See Fig. 2.) The pathological condition is really a double one. There are

both *spasm* and *dilatation*. These two entities and various descriptive adjectives give rise to the different names cited above.

Experiments show that stimulation of the peripheral ends of the vagi causes dilatation of the

FIG. 3.—Front x-ray view of Case I immediately after lavage and a bismuth meal. (Picture by Dr. R. H. Boggs.)

cardia and contraction of the walls of the esophagus, but that cutting of these nerves has the opposite effect. These phenomena may throw some light on the origin of this condition—but how?

It has been suggested, with a good deal of reason, I think, that in these cases there is always an underlying pathological condition, possibly congenital of the autonomous nervous system, and when we understand this system better we shall know more about the causes of spasm and dilatation of the esophagus. The direct cause is often unknown, too, but sometimes appears to be undue haste in eating or overacidity of the stomach.

As in many diseases, the first references to this condition were vague. It seems to have first been observed in autopsies and later was occasionally recognized by the use of bougies, by the sounds of delayed deglutition, etc., but it was not until the esophagoscope was used that much attention was paid to it. Still later by the use of x-ray pictures the condition has become moderately well known. Purton reported one of the first cases in 1821. Seventeen case-reports were gathered up in 1878 by Zenker and von Ziemssen, and a number of other writers described other cases in increasing numbers, until Mikulicz mentions a hundred cases reported up to 1904. Since then many have been reported by various observers, among them Einhorn, Plummer, Sippy, Meyer, and others in this country. Some two or three hundred cases altogether have now been reported under various names. Compared with the forty cases described by Plummer, and the ten cases detailed by the late Jesse Meyer in 1910, my experience with three cases has not been great, but I hope gives me reason for writing about a subject to which I have given a good deal of consideration.

The chief complaints of these patients are of inability to swallow freely, and of the regurgitation of food. Before proper diagnosis is made they usually have learned to force the food down (often after drinking water).

The descriptions by these patients of their symp-

toms make one think at first of neurosis of the stomach, hourglass stomach, or some other *gastric* disorder; but more careful investigation differentiates the trouble from these conditions. When this comparatively rare complaint once comes into the mind of the physician, the diagnosis is comparatively easy. It is quite necessary to confirm the diagnosis by either an endoscopic examination or an x-ray picture. With the endoscope or esophagoscope in skilled hands a diagnosis of this condition can often be quickly made. The x-ray picture should be made when the gullet is as empty as possible and immediately after a "bismuth meal."

In a number of cases the true nature of the disease has not been recognized, and because of the "vomiting" and epigastric pain gastroenterostomy or appendectomy have been performed. A dilated esophagus may be found at autopsy when no symptoms have been noticed during life.

There is a sense of stoppage or fullness under the lower part of the sternum, and later in the disease this may become actual pain radiating to the back or shoulders. The regurgitation is different from a true vomiting. The patients say "the food just comes up," usually without warning. While the patient is asleep the liquid contents of the dilated portion or sac may appear in the mouth or wet the pillow. If this food comes up soon after swallowing it has its own proper taste, but if it accumulates in a large pouch, it becomes sour or even fetid. There is an increased secretion of mucus, which, mixed with the undigested food, looks quite unlike true vomitus.

The curability of these cases is in inverse ratio to the duration, that is, the earlier the condition is recognized the better the prognosis. The more extensive the dilatation or the sac formed the less is the probability that the esophagus will regain its normal size and tone. If these patients are fortunate enough to have the condition recognized within a few weeks or months after its beginning, they can be benefited to such an extent that with

FIG. 4.—Lateral x-ray view of Case II, taken immediately after a bismuth meal, and showing large spindle shaped dilatation of esophagus. (Picture by Dr. R. H. Boggs.)

careful eating and drinking the condition gives little or no trouble. Even if the patients are not cured, the relief after proper treatment is so great that they are much pleased with the results. If a case is treated as a neurosis of the stomach month

after month, if forced feeding is advised until the condition has lasted a year or over, and if the dilatation has increased in size until it holds 6 to 8 oz. or more, then the prognosis is not good, and only by frequent washing out and most careful dieting and living can the patient be kept moderately comfortable. Even then some serious operation or fatal termination is always imminent.

In Dr. Jackson's skilled hands the divulsion or dilatation of the strictures has been successful in helping or curing these patients. He prefers the divulser of Mosher inserted through the esophagoscope.

In 1898 Russel reported (*British Medical Journal*, June 4) a number of cases of this complaint treated with a silk covered rubber balloon, and in 1906 Sippy reported before the American Medical Association a series of cases treated in this way.

In treating these cases I first pass an ordinary stomach tube well down into the esophagus and thus enable the patient to empty the dilatation; then by thorough lavage the gullet is washed clean.

FIG. 3.—Front view of Case II taken 7 hours after dilatation. Note distention at lower end of esophagus at top of picture. (Dr. R. H. Beers.)

This alone gives great relief. Next the dilator is introduced.

This dilator resembles those used by Plummer, Meyer, and others. It is made on an ordinary closed-end tube, near the tip of which about 5 inches of seamless rubber dam tubing ("Penrose drainage tubing," 1 to 1½ inches in diameter) is firmly fastened with a neat winding of sewing silk, leaving exposed the rounded end of the tube, but enclosing the "eyes" or openings. Next a sausage shaped bag made of thin but strong dress silk is slipped on and fastened in the same way, and then another length (slightly longer) of rubber dam tubing is put on in the same manner. Now if air or water is forced into this tube, it escapes through the "eyes" into the rubber bag which was first applied, and then the apparatus looks exactly like a link of sausage with a stomach tube passing through its long axis.

A mandrin of dentist's cable assists in the introduction of this instrument, in fact is usually required. In recent cases this dilator can be passed through the stricture quite readily, but in the cases of longer standing (probably a year or more) the bottom of the dilatation gets broad and flat so that

the mandrin is necessary and the introduction is a tedious operation.

When the tip of the dilator slips through the stricture, the patient can distinctly feel it do so, and the operator, too, can feel it. The mandrin is then withdrawn with a continuous turning as though it were being unscrewed. The tube is held firmly with the other hand to prevent its withdrawal along with the mandrin.

Next a stout syringe filled with *warm* water is fastened to the dilator and the water is forced in. In the author's experience no manometer is needed, for the patient feels any over-distention (which the silk bag in the dilator should prevent). Moreover, a stomach tube is used as a foundation for this dilator which is but 50 cm. long and has 20 cm. of soft rubber tubing of the same diameter vulcanized onto it; the syringe nozzle fits into this mouth piece which by its stiffening shows the pressure accurately enough. When filled with water from the syringe, this tube is pinched, the syringe laid aside, and a pinch-cock slipped on to retain the water, *still under pressure*. The patient sits with this in place for five or more minutes, then the water is released and the instrument withdrawn.

CASE I.—A stout meat merchant, married, was referred to me in October, 1910. Family history and habits good. He had worked hard and was of a rather nervous disposition. For years he had weighed 210 to 240 pounds. In 1907 he noticed slight indigestion at times for about six months and then developed an ordinary case of typhoid fever. About the time he fully recovered, he began to have a feeling of pressure in his chest and of choking on eating, but no nausea or pain. The trouble has since been practically continuous. Often while eating the food will seem to stop, causing choking and increased distress until he brings on "vomiting." This gives relief. Every few days an increased full feeling and general malaise causes him to empty esophagus of its contents along with much ropy mucus. Patient often "vomits" a quart including food eaten the previous day. He locates the choking at the tip of sternum and sometimes has a dry cough and hemicrania when the fullness is at its worst. Acid foods bring on the trouble at once, and also salads, sauerkraut, cabbage, many potatoes, coffee or milk. Physical examination shows nothing except a tremulous gray coated tongue and some tenderness in the epigastrium. Weight 228 pounds. Five hours after an ordinary breakfast a stomach tube withdraws a watery fluid with a floury layer. Little mucus present. HCl absent; total acidity, 26 parts per 1,000.

October 18, 1910, Ewald fifty minutes, HCl absent; acidity 10. Diagnosis as yet unsuspected. Treated for chronic anacid gastritis. November 12, patient gave me one ounce of matter "vomited" 7½ hours after supper; no HCl.

November 14, drank cold water in my office. This choked him and as he forced it into stomach, stethoscope over tip of sternum heard squirting sound. November 25, stomach tube withdrew watery liquid much like the chyme after an Ewald test breakfast, HCl absent. Then the true condition dawned on me and I began lavage and passing hard rubber bougies, with rapid improvement in the general feeling. An x-ray plate showed an enormous dilatation of the esophagus. (Fig. 3).

January 1, 1911, I began to use the soft rubber dilator described above. This patient was under my care for a year. General health became very good, and he was very comfortable with weekly treatments. Once or twice when he took cold, and once when his store was robbed, he had more trouble in forcing food into his stomach and the dilator did not enter the stomach so easily.

Through 1913 I hardly saw him. He kept himself comfortable by emptying out his esophagus two or three times a week. In January, 1914, he took cold which made him decidedly worse. He got absolutely no food or liquid into his stomach for twenty-four hours, and the pain near the tip of the sternum became so acute that he could not straighten up; but lavage and passing

the dilator made him feel much better at once, and a few treatments made him feel as well as in the past year.

This patient is now comfortable, but his esophageal condition is, I believe, worse than when I first saw him. I am trying to have him undergo esophagogastronomy.

CASE II.—A merchant of 40, single, consulted me in August, 1914, complaining chiefly of loss of weight, sense of fullness in chest and regurgitation. Family history negative. Personal history negative except hay fever. Habits good. Former weight 155 pounds. Trouble began suddenly eight or nine months before, and no cause could be found. Ate ordinary supper and was well when he retired. Awoke at 1 or 2 A. M. with liquid in mouth; then symptoms continued. Said that six months before seeing me, x-ray pictures were taken and pyloric stenosis suspected. Operation showed a normal stomach, but appendix was removed; no improvement resulted. Later had slight pleurisy. Ate generally, but melon or raw fruit "would not go down." Physical examination negative. Weight, 123.

After no breakfast, tube withdrew several drams water with white flakes (evidently from esophagus). Congo negative; HCl absent; total acidity, 96 parts per 1,000; lactic acid present. Ewald test breakfast, one hour; HCl 20; total acidity, 36.

Diagnosis: Dilatation of esophagus. Dr. R. H. Boggs took x-ray pictures which showed a spindle-shaped dilatation of the lower end of the esophagus. (Figs. 4 and 5.) Sept. 1, breakfast food at 7 A. M. Tube removed 8½ ounces from esophagus at 9.30. Congo, negative, 2½ per cent. sugar present. Began use of rubber dilator.

Treatment continued a year and a half beginning with three and four days intervals and increasing to intervals of fifteen to twenty days. Soon food was swallowed more easily; the dilated portion decreased in capacity (0 to 2 or 3 ounces), and the body weight increased 30 pounds. If the intervals between treatments were lengthened too rapidly the symptoms tended to return. In August, 1915, he went camping for two weeks. Had no treatments, but was so well that none of his companions suspected his trouble.

In November, 1915, the patient looks and feels well except that after most of his meals he feels a fullness in the chest which is easily relieved by swallowing or by drinking a glass of water.

CASE III.—G. K., a seamstress of 34, single, was seen by me in April, 1915, through the courtesy of Dr. Chevalier Jackson. Her chief complaint was the regurgitation of food. Family and personal history negative. This trouble began in 1908 with difficulty in swallowing liquids and regurgitation at night. Trouble continuous and in December 1914 she was referred to Dr. Jackson who diagnosed the condition with the aid of the esophagoscope and began treatment. Her circumstances admitted of only occasional visits to Pittsburgh when she was always benefited by mechanical dilatation of the stricture through the endoscope. Patient ate everything and appeared well. Would finish meal and then she would feel esophagus full. Then by repeated "swallowing of air" got food into stomach. Liquids harder to swallow than solids.

In September, 1915, she reported by letter to Dr. Jackson that she had been "feeling real well all summer." No hard choking spells and greatly benefited by the treatment.

Remarks.—The early diagnosis of this condition is most important, for the earlier proper treatment is begun the better is the prospect of cure.

The esophagoscope shows this condition at once and very plainly. An x-ray picture of the chest after a bismuth meal is an excellent aid to diagnosis. The withdrawal of the stomach contents at one time with the tube and at other times the withdrawal of undigested food with lactic acid should put the physician on the alert.

When one "draws in" his breath, the lungs passively expand to fill the dilated chest, i.e. there is a negative pressure in the lungs and esophagus. If a tube is inserted in the dilated esophagus, air goes in and out with the breathing, and if the end of the tube is held in a glass of water, the liquid is drawn into the esophagus when air is drawn into the lungs. If the tube is in the stomach, just the opposite takes place.

In the dilatation the conditions are ideal for the development of lactic acid which is almost always present. On the other hand, HCl is present (normally) when the stomach is entered and true chyme obtained.

Slight nervous irritation will usually aggravate this condition.

The dilator should be distended with warm water at or a little above blood heat. This is certainly best to relax a spasmodic stricture.

The distended dilator should remain in place at least five minutes. Case II improved most rapidly just after this was begun.

In the treatment of these cases patience is required. While some of the people are cured in a few treatments, many of them are benefited only by prolonged and patient care.

WESTINGHOUSE BUILDING.

TREATMENT OF RHEUMATIC FEVER.*

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

IN the treatment of rheumatic fever, despite all the advances of knowledge during the past few years, we have not improved upon the use of the salicylates.

It is true we no longer regard them as specifics, but we have, as yet, no other agent which relieves acute pain of the affected joints so rapidly and considerably. In addition, when the fever is high and maybe threatening, they lower it at the same time. But the salicylates are objectionable frequently. Given in large doses they are apt, after a few days, to cause annoying symptoms like headache, dizziness, nausea, a weak, irregular pulse, buzzing in the ears, general depression. To not a few patients we are compelled very soon to diminish the amount or the frequency of the dose, and although the patient is still suffering, feverish, and with several of the larger joints swollen and painful.

In view of these facts it has seemed well to stop their use by the mouth at times and give them either by the rectum, as injections, or hypodermically, through the veins. They cause irritation and swelling when given subcutaneously.

To Dr. Lewis A. Conner¹ we owe as, I believe, the best study of the intravenous injections of the salicylates, when from one cause or another either the stomach is rebellious, or the attack is serious and demands rapid and efficient doing. Notably, the brain, the heart, hyperpyrexia, unusual distress, or the involvement of the eyes, may be indications in this direction.

To obtain the best results a small, sharp needle should be used and the chemically pure salicylate of sodium is preferable. The dose may be 10 to 20 grains in a 20 per cent. solution, and the injection repeated in twelve hours, or three times in twenty-four hours, if required.

With proper care as to local sterilization by painting with tincture of iodine, there are no un-

*Read before The Practitioners' Society of New York, November 5, 1915.

toward sequels. Despite Dr. Conner's experience, I would favor, preferably, if I abandoned giving a salicylate by the mouth, the use of it by the rectum.²

This method is easily available and requires no special skill or doing. A preparatory soapsuds enema is all that is required before the solution of the salicylate is injected. The amount of the salt dissolved in a few ounces of water with the addition of 15 minims of tincture of opium, may be as much as 2 drachms, and the injection may be repeated, if required once again, in twelve hours.

The amount of the salicylates to be given intelligently will depend upon the view we have of their action and of the effects produced. To some who regard them as specifics in rheumatic fever, large, frequent doses are essential to obtain good results. To others, who still regard them only in a measure as specifics, such doses are not desirable, and the best results are obtained when 10 to 20 grains of the soda or ammonia salt are given by the mouth every three or four hours. I, personally, share the views of the latter. I also believe it is wisdom to combine with their use an equal amount of bicarbonate of soda, either given with the salicylate, or else between times. Often, drinking freely of Celestins Vichy water seems to me preferable to any other way of introducing soda into the system.

To those who prefer a potash salt on account of its diuretic properties, the citrate in 20-grain doses in solution with a little lemon juice added is preferable.

As regards the salicylates, I much prefer the ammonia salt to the soda salicylate. It may be given in the same dose, but it is surely more stimulating and agrees better with the stomach and following its use, has fewer unpleasant symptoms. Preferably, however, to the ammonia salt and as soon as the pains in the joints in adults have diminished, I greatly prefer salicin to any other salicylate. It is a tonic; it agrees with the stomach and may be given frequently and in relatively large doses, 10 to 20 grains, every two hours, without any attendant risk.

Whenever the heart is weakened, or slightly dilated and a murmur exists, this alkaloid is especially serviceable. While I do not endorse the miasmatic views of MacLagan in regard to its value, I have little doubt that in very much he is, even to-day, therapeutically correct. I am of the opinion that the late Dr. Austin Flint's experience corroborated many of MacLagan's affirmations. I have never been convinced that the use of wintergreen oil was preferable to the salicylate of sodium, or ammonium. At one time, as we know, Dr. F. P. Kinnicutt made frequent use of it.

To me, the best combination internally, in the treatment of rheumatic fever, is salicylate of ammonium, five to ten grains, phenacetin one to two grains, caffeine one-half to one grain, every two to three hours in two capsules, at the beginning of an acute attack. Later, it may be given every three or four hours—or three times in twenty-four hours.

I have made use of this same combination with the happiest results, for many years, in attacks of influenza and have continued its use for several days. I am quite sure in both diseases it exercises an antimicrobial effect so far as the general pains and the high temperatures are concerned. I do not believe it has much effect in rheumatic fever, in warding off heart complications. At least, this is true whenever no other salt of sodium, or potassium,

is taken at the same time. When it is, I have the impression that heart complications are less frequent, or less severe. Certainly there was much in favor of the old alkaline treatment of rheumatism, and particularly from the heart point of view.

It is to the combined treatment with the salicylate that we obtain, as Lees has abundantly shown, our best remedial effects. After all that may be said in the way of remedial treatment, in rheumatic fever, it is a most distressing, obstinate affection. Just when we seem to get the better of it, it crops up again, and whether we regard these exacerbations, as relapses, or reinfections, they are none the less disheartening. Even during the attack and as far as may be proper, we should search for the focus which has caused it and treat it with good judgment.

If it be in the nose, or throat, a suitable antiseptic spray, or gargle, may be really useful, and lessen somewhat the virulence of the attack. What is true of the nose, or throat, is true of the mouth, and an antiseptic mouth wash, such as Wadsworth's, may be an important factor in keeping the mouth in good shape, especially when the teeth and gums are evidently the source of absorption of many pernicious organisms. The true, efficient treatment from this point of view is the preventive one, which has in view the rheumatic attack before it has occurred.

No child to-day should have offensive catarrh, obstructed nasal passages, adenoid growths, or enlarged or diseased tonsils without having them duly considered and cared for. An operation is not always required, but occasionally it is. When this is true, delay is wrong and should not be permitted. Independently of an operation much may be done with appropriate local treatment to put the nose and throat in better shape. So it is with the teeth. If they are decayed they should be filled. If they cannot be filled they should be extracted. In any event the regular use of the tooth brush, waxed dental floss, and a suitable dental paste and tooth wash must be insisted upon. No doubt, in a proportion of cases, not small, the dyscrasic, or constitutional condition, is present as a producing cause in rheumatic fever.

Still it is far from being omnipresent. What is clearer to-day and generally admitted, is that rheumatic fever is an infection caused by a special micrococcus, or by more than one streptococcus, or other infective germ. These are absorbed constantly from a diseased focus and show their evil effects especially when the system is debilitated and susceptible from any cause. This cause may be bad surroundings, such as lack of sunlight, dampness, insufficient air space. Poor food, and that, too, in quantity inadequate to bodily needs, may also be a very important, efficient cause of an attack of rheumatic fever. Certain it is, that among the well-to-do, who suffer from no such deplorable conditions, rheumatic fever is far less frequent.

While among adults, all such conditions should be effectually combated, they do not have the immense importance they have among the young. What sadder sight is there even for the older physician than the view of the little child bound to its bed, suffering from constant dyspnea and unable to move, or even eat, or sleep, without some addition to already existing pains. These symptoms are in part only the index, as it were, of the rheumatic infection and poisoning as it affects the heart. We have before us the enlarged, tumultuously acting

heart, unable to respond to the calls made upon it to preserve life, or well-being. These little ones do not always die immediately, or very soon. But they have before them months, or years, of distress and disability, and ultimate cure is usually most difficult, or well-nigh impossible.

To no one more than to Dr. George M. Swift⁴ do we owe an instructive, enlightening account of carditis among children as observed by him at St. Mary's Hospital, New York.

Again, to Poynton and Paine⁴ we also are greatly indebted for their insistence upon the great value and importance of all those prophylactic measures which should be instituted to give our poorer children the opportunity to escape from the dire perils of an insidious and terrible disease.

As they remark, how true is it that so very much has been done for those threatened, or attacked with tuberculosis, and how very little relatively, for those threatened with, or attacked by rheumatic fever. Just as we need sanatoria, and desirable surroundings for the tuberculous, so we very much need proper convalescent homes for cardiac sufferers among both the young and the old. They cannot work at any active employment again when they leave the hospitals. They absolutely require prolonged rest, very few, graduated exercises at a given time, assimilable, nutritious food, and the most judicious, careful medical management.

Who will look after this in a practical way? Who will give the money to fit up and endow a large special hospital in a healthy site, with warm, dry air, for all such?

It is needed for the race, present and prospective, more perhaps than any other thing I have now in mind.

In view of the imperfect and limited good which we have been able to accomplish with our treatment of rheumatic fever with the salicylates and alkalis, we have in later years had recourse to serums and vaccines. The former have thus far not succeeded, even in a few cases, in producing any very notable or advantageous results. Many times they have been followed by local, or general disturbance which has occasioned not a little natural anxiety. The skin specially has been recalcitrant, and an angry erythematous rash accompanied by chills and fever has been witnessed by the experimenters. In the minds of the men we should rely on, these trials are not considered advisable. Perhaps we may speak somewhat more confidently about the use of vaccines. They have been of distinct service in several well recorded cases,—but they, too, have their drawbacks and their uncertainties. Whenever a culture can be obtained from an evident focus of infection and made use of after due development, in a case where the salicylates are inoperative, they may not be objectionable and should be tried with every precaution.

To begin with, we should make use of a very moderate amount of any particular vaccine, and little by little test its tolerance to the individual. As to those vaccines which are called polyvalent and are the combination of more than one poisonous microbe derivative, it seems as though it were a very uncertain and irrational method of treatment. If one special micrococcus develops an antibody which may be curative, how can the others be of service? If not of use, may they not be harmful? With such a mixture of microbes, how can we make use of the really valuable microbe in sufficient quantity and not inject into the patient's system a great number

which are inert, or injurious? To many observers the problem has become additionally difficult, because the vaccine and the salicylate have been employed simultaneously, and to assign to one or the other the good or bad effects brought on is simply beyond our powers of judgment.

To sum up this matter by quotation from a prominent scientist, I would add: "In the acute stage of the disease [rheumatic fever], the only time when joint cultures will yield positive results, the usual vaccine treatment does the least amount of good and is accompanied with distinctly greater local and constitutional reaction than during convalescence and after all symptoms have subsided." Further, "in cases where salicylates fail to do good the vaccine usually also has little, or no beneficial, action."

In regard to local treatment during the acute attack, I wish to make special emphasis as to the importance of keeping the inflamed joint, or joints, at rest, so far as possible. This is done by means of a well fitting, padded splint, in felt or plaster, for the knee or ankle. For the shoulder, or elbow, a proper supporting cushion or pillow is about the best we can do. The support must not be too soft and yielding. The joints or joints affected should be directly covered with cotton batting, and with thin rubber, or oil silk outside and held in place by a light flannel or gauze bandage.

Warm lotions with bicarbonate of sodium and laudanum may be applied on lint or layers of gauze to subdue the pain; provided they don't interfere with the support obtained from the splint, or necessitate frequent changes, which cause great pain through unavoidable movements.

I deprecate absolutely the application of iced cloths or an ice bag to the inflamed rheumatic joint in its acute stage. In this way, I am confident, a lamentable and dangerous metastasis may be caused to the heart or lungs. Further, I object most strenuously to what is now frequently practised, namely, the application of an ice bag interruptedly, or continuously, to the region of an over-acting heart, where a murmur or friction sound may already indicate the beginning of endocarditis, or pericarditis, or indeed, the involvement of all the heart structures, including the myocardium.

No doubt pain, if there is any, is thus subdued and the frequency of the heart beats lessened, but to me the old custom of a warm mush, or flaxseed poultice, or warm applications similar to those suitable to inflamed joints, are far preferable. They soothe and quiet quite as well, I believe, and are freer from attendant, and possibly very unfortunate sequels. To see a poor, weak, anemic, suffering child, or adult, with an ice bag over the heart, always upsets me, and simply because I believe it is irrational, bad practice, and may occasion very harmful consequences, mainly in the direction of a metastasis to the lungs, or nerve centers, without being of any real or lasting advantage to the heart itself. The old time so-called inflamed heart is not in reality inflamed; it is simply suffering from an acute infection carried to it through its arterial supply and also from the resulting toxemia. This, Dr. George M. Swith has shown, as I believe, most clearly and graphically.

During the semi-convalescent period, locally, the joints may be gently massaged with great advantage, with or without the addition of mutton suet, camphor, or soap liniment. Passive movements may also be utilized in like manner. At first, and if the joints do not yet bear movements, or even

massage treatment well, an application of turpentine and soap linament sprinkled on flannel, equal parts, may be merely laid upon the painful joint. If evaporation be prevented by means of rubber tissue, or oil silk, blistering may be produced. This result at later stages of the disease is often useful, and turpentine, as in the case of tonsillar inflammation, when locally applied, has appeared to me to have a somewhat specific effect.

As to the use of superheated dry air treatment at this stage of the disease, I have little doubt that in some cases it is very desirable in lessening pain and securing more pliability to joints which have been previously acutely inflamed. To secure the best results it should be followed frequently by gentle and skillful massage—and done daily, or every other day, in a properly equipped establishment, where the patient has the services of an operator who has experience and knowledge. Even in hospitals this can rarely be had. It is most exceptional in any private house, where it could only be obtained by considerable expense and with great difficulty. It would become then a question also as to its real and lasting utility and to what extent one should insist upon its sufficient trial.

Electricity in one form or another has been vaunted by the enthusiasts in sub-acute forms of rheumatism. The x-ray, the rapidly interrupted current, have both been used and with excellent results, as reported by the specialists. About these results I am still somewhat sceptical. In one very serious and obstinate case, however, I now recall, I am confident static electricity was very beneficial when other methods had failed to relieve.

As to diet and clothing, a few remarks may be not out of place. I am convinced that too restricted nutriment is a mistake. Of course, a liquid diet in the initial stage is necessary. But even then there is no reason why a little tea, or coffee and milk, milk flavored, or prepared in different ways, jellies, broths—perhaps a little milk toast, or an egg may not be allowed, particularly if the patient is much run down and very weak. A little good old brandy or whiskey, also, will be very useful, given in small repeated doses. Despite all theories which oppose their employment, clinically they are very helpful to tide over a few days of great stress.

Later, when the fever and pains have subsided, in part at least, any simple, well prepared food in moderate quantity at one time which the patient's appetite craves is, as a rule, permissible.

The patient should wear an undergarment or nightshirt of wool or silk. Preferably, also, he should be between woolen blankets, and not between sheets, even of cotton, in the acute stage of the disease. Unnecessary and too frequent exposures of the chest to examine for changes in heart murmurs, or for more or fewer râles in the lungs, or pleuræ, are deplored. Only movements that are absolutely required should be permitted. Meddlesome interference on the part either of doctors or nurses is objectionable. Great care and gentleness should always be the watch-word.

Management of the bowels so as to obtain proper evacuations without causing much distress is often a difficult task. Cascara by the mouth is our most helpful drug, as required.

During convalescence the one thing to be avoided is too rapid return to walking or to work, and before the heart has recovered from the rheumatic poisoning, so-called, which really means microbic infection of one or other sort. The period of com-

plete rest after all acute symptoms have disappeared should be several weeks on an average. To resume work or movements except a very mild kind, and especially in the case of young people, is almost suicidal short of this period. It is not a question of a heart murmur, but it is a question of a heart muscle which has suffered dilatation and loss of power through infection.

Among the tonics which I hold as most valuable to restore health and strength to the patient, I know of none equal to a combination of the glycerophosphates of lime and soda with kola and cinchona. To ward off future attacks and complete the cure, a few weeks at the Hot, or White Sulphur springs of Virginia, for those whose means permit it, is much to be desired. Formerly a trip abroad in the summer and a cure at Aix-les-Bains, followed by a few weeks in the Swiss mountains, was what seemed most desirable. If the general health is kept up to the highest point a second attack is not so likely to occur, even in young boys or girls. Seemingly, the cardiac disablement which follows an attack of severe chorea is more than that subsequent to an attack of rheumatic fever, in which chorea has not occurred. In these instances a longer period of complete rest and, even greater, more continuous care is very essential to a complete return to normal health.

When other means fail and even prolonged rest, massage, passive movements, graduated exercises, do not re-establish a weak, dilated heart, the Nauheim treatment abroad, or at home, is a final resort of great value. It must be employed, however, with rare good judgment and knowledge to obtain valuable, enduring results. Otherwise, I believe, it is deceiving and harmful.

THE INCEST EPIC OF THE FREUDIANS.

BY GEORGE MITCHELL PARKER, M.D.

NEW YORK

THE door into the nursery was open. The mother saw it. "Always we should have it closed in the morning and you had said it was when we awoke." The father rose. "It was closed—ah"—the door flashed back and past his father rushed the boy. With a leap he was in the mother's arms, the four-year old Paul. He was disturbed and cried: "I do not want my father to come here—I do not want him—he would hurt you and you are mine. When will he go away, so that I may sleep here with you alone?"

Now this father and mother read all the magazines or nearly all the magazines and especially they had clustered most intimately about such articles as inform one of the wonders of science in their application to mankind. Singularly all conveyed a certain implication that in some way a betterment was on its way. They were to be helped; life was to be made easier and richer. Science would do this for them and their children. Science had become a kind of foster parent. The old theological concept of the Great Artificer was rapidly

merging into a flux of test tubes and instruments of precision. Only the kindly emphasis still lay upon the care and solicitude for the reader. The articles were pleasant and easy to understand and sufficiently diverse to maintain a ready attention. With a contented spirit they shared their knowledge of cancer and Montessori, of Salvorsan and Gary Schools. Both knew the entire truth as to alcohol and twilight sleep and were happy in their conjoint possessions.

Yet, up to the present moment, this knowledge had been without interest; they had not been able to find its application in their lives. Inwardly both had mourned the absence of a personal message beneath a quite fictitious complacency in the soundness of their vital arrangements. But now the message had come. Little Paul was carried back to his brother Rudolph and his sister Frieda, whose careers we must wrongly slight that Paul may receive the illumination to burst forth from his father and mother as the door closed upon his pitiful figure. "Œdippus," moaned the father; "Incest," the mother whispered. "And in our child"—the fascination of the terrible fulfillment of the prophecy. Both knew they were in the presence of the original apple of the original tree of knowledge, for a newer folk-lore had left no vagueness as to the meanings of biblical symbols to this enlightened pair. Both knew nothing in the sky nor on the earth nor in the sea which did not portray sex; neither that made by God nor hewn by man lacked it. The sun, the moon, the fruit, the flowers, the insects which sucked their juices, the beasts which trampled them under foot, the fish, the water, the tides, the steeples of churches, the stairs, the chimney, the closet, the drawers, the hats, the canes, the rings, all—all marked off to the discerning eye the various objects which a generation earlier had been given to see but in a few and painfully obvious similarities. Theirs now was a richer and wider knowledge. To them Incest stood forth as the core of life, never attained nor attainable, yet ever desired; banished to a part of mind which an apt intelligence had grasped with a localizing sense so keen that the unconscious took a vision of a clear hinterland, inhabited by strange creatures occasionally forcing a way through an intervening space into the city of life. And the life in this city was made always to adjust itself to the inhabitants of the hinterland. At first this seemed strange, that the adjustment should not be to the city; but both soon felt the greater mystery and truth inherent in the former conception, for did it not contain the ripest product of Science? Only it had been difficult to dig up affirmatory data from their own lives. Yet here in their child was the Infantile Libido and for the first time they seemed to grasp a meaning which much writing had not made plain. They saw now that the qualifying adjective "sexualis" must be given it. This was another point upon which they had stuck; that sex, as sex expression toward sex, could be so early in its exit. Psychosexual as a term had not helped much. Yet the structure of this system of life had predicated sex the basic, with hunger and a few other instincts as quite subordinate and derivative. It had, of course, been their misfortune to gain this knowledge long after the nursing period. Both had regretted the impossibility of having seen the Libido in its emergence when the infant lips had first seized the mother's breast. To be sure, little Paul had wet his bed rather longer than had his

brother Rudolph; also he had been a restless sleeper and a child demanding much care from the mother. Yet this never seemed quite clear cut. Certainly it had lacked the exhilarating dramatic element of the Major Revelation.

It is inherent in a revelation to disclose; and to the parents this morning had defined the past and laid bare the future of their little Paul. They saw now the error under which mankind had staggered in the conception that the nursing child is dominated by a tropism leading the lips to the breast whose flow inexorably induced the reflex of swallowing. The amiable experiments of comparative psychologists on the chick, apparently showing the existence of this reflex, the studies of Loeb, which, again, apparently demonstrated that tropism involving the juxtaposition of bodily surfaces, all these now were false. Too plainly the lips were real erogenous zones, which sought the mother's breast for a psychosensual pleasure to which the hunger was a codicil, emphasizing but not initiating. Little Paul, an infant, had been driven by the same tendencies which, later, were to make him, presumably, a factor in the perpetuation of his race. The mother had now to abandon finally a feeling that her infant's calm and happiness found in the mother's arms meant to him a simple satisfaction in being cared for, of being in a safety zone. She could now only see in this attitude a satisfied Libido, a psychosexually satiated organism. Every care given him had intensified the Libido of the child for the mother, this Libido Sexualis. That bed wetting meant a repressed eroticism now was plain. She saw that the care and personal attention subsequent to this was again but giving to the child his object of desire which so plainly emerged in an act standing for a deeper sexual relation. The restlessness at night, the importuning for the mother's presence was the beckoning of an inarticulate Incest.

But now it had spoken and tragedy enveloped them from that Greek drama in which the voice of poetry had been silenced by the louder threnody of Science. Æschylus had become the psychoanalyst; poetry the handmaid of Science. If life is sex, then the core of life is the incest complex. In every creature this is immutable. The unfulfilled incest was the original unfulfilled wish, hence to be banished as years come on to the hinterland of the unconscious. Here it would breed a demon herd to invade the fair city of the conscious life until it came to be exorcised by the analyst. The adventures of these modern knights had especially held the parents. Certain ones possessed evident fascination, for they had appeared in different articles, approaching in this the actuality of an Arthurian ballad told the child where the dragon is overcome at the same point and at the same time every evening. They knew each dream, unriddled, led through a vast labyrinth back to the core of incest unfulfilled. In a humble way they had marveled at the extraordinary facility which delved to the bottom in each cup of a word for meanings centuries old, for symbolisms left far behind by civilization, each brought upward by the delving analyst to confront the dreamer with the proof that his unconscious, in some way, had inherited treasures consciously never met with. It confounded the dreamer that always the trail led back to the unhallowed desire for father or mother. Nor could he protest, for even the protest registered only

a shame at sex, the sign of blood guilt, psychologically. No red herring could lift the nose from that spoor which ran to sex. Physical symptoms as a toothache or a neuritis, a joint rigidity, head pains, abdominal cramps, all these they had seen the analyst throw within the hopper to emerge as successive links of a monstrous but impressive string of sexual sausages. The more unusual symptoms of fear or compulsions or anxieties yielded the same product but more readily. There was less of physical nonsense here to override. Personal characteristics as miserliness, aggressiveness, delicacy of demeanor or attire indicated latent tendencies of a kind to exclude the carrier from ordinary society. And all of these things their boy might carry; all of these things their boy might be, for all expressed various compromises with the unfulfilled wish for incest which this morning had shown.

Yet beyond their boy were other boys and beyond these more and the world. An incestuous world, an incestuous society; to mend this a small and devoted band of scientists who were to teach mankind that life is made up of an adjustment to an ungained but ever-desired incest, residing in a place consecrated for itself, that here it might find pleasure in its being. Health came only in accepting the belief of this presence. Confessedly, this process was difficult for the usual person. Even the analyst granted that few were able to rise in a free flight so far above the structure of culture. Their emphasis lay upon the necessity of an individual induction into a range of ideas out of which the incest concept might crystallize. It had not been difficult with this point of view for the parents to understand, as necessary, the rather unpleasant procedure of an analysis which converted all individual life into a homogeneous medium of sex terms, for only out of such a saturated solution of sex could crystallize the pure and iridescent crystals of the incest motive.

Yet here was this dominant motive dislocated into the unconscious, driven there by society, and still by science so placed that extensive pilgrimages were recommended thither that, in his treatment, the individual might exclaim to this squatting Buddha of Power, "Most Powerful, we acknowledge Thee and beseech Thee that we may make our lives ever adjusted to Thy Presence." Perhaps their honest bourgeois minds did not do quite this, despite a rabid and unsatisfied desire to believe in something. Indeed, they did halt and fail to see why society should have carried out an exile if this incest motive were real and not fictitious. On the one hand, it must be real, if health demanded an adjustment to it. But, if it were real, then what about this very matter-of-fact world where a living was to be made, laws enacted and meals ordered? So far as society, the lessee of this world, had expressed herself, there had been laid down a more or less straight rule that things which were real always had adjusted themselves to other realities. The things which were fictitious had been relegated to limbo. It seemed an isle of safety that the unconscious was this limbo. But if this were so, how could the majestic Œdippus, sole resident and taxpayer in this land of the fictitious, how could he be viewed as real? This was where belief took their moist palms and led them on, reiterating the necessity of adjusting their lives at this throne, even though their garden instincts made them see it lacked utterly that reality which Walt Whitman divined in the frost upon a burr.

It is not a little unsettling to find oneself wholly wrong after many years of fairly even endeavor. Yet Paul's parents faced this bravely. They had adjusted to nothing but reality and a most real outer world. Of some gaps in their composition they had been well enough aware. Many desires had failed them, but they had laid few flowers on the graves of their unfulfilled wishes. Now they must exhume these and peer into the vestiges to see, as reality, the dread lines of an incest—if they would be well. Plainly, they never had taken a breath of health. Until now they never had sacrificed to Œdippus. Unfortunates, they had walked with society, let it be with a halt or blurred vision, here had been their place. They had sacrificed to Themis as had all others. Indeed, when the precedents of their past conduct enveloped them in the history of man, painfully and imperfectly but honestly adjusting, they found themselves sliding back from the "feste burg of incest." "In a practical way, just how could the knowledge of this Œdippus concept have aided in piling up the humble structure of a drug business"—and then the accusation fell from the open, "Think why you chose this work; has it not all to do with the pestle and mortar," symbols which colored the face of the father as he thought of the unworthy motives which must have unconsciously driven him, impelled by the incest desire, to express his sexual aspirations under the cloak of a vocation into which he had thought himself inducted through a combination of economic need and the fortuitous death of the only druggist in his little town. All his study, all his application had been at the behest of this one motive—the one reality. Also the butcher—he shuddered at the sadistic impulses harbored by this fat and pleasant citizen who smelled of nothing worse than suet to any nose but an analyst's. The baker with the rolls, the photographer, was there not here a plainly-marked exhibitionism? The dentist and his secret desires satisfied with each painful tooth extracted by the pliers; Jerry, who sold cigars, with hidden homosexual longings in the dusty cases of his Regalias; they were all quite as bad off as he and society as rotten. A bitter grief caught him, as he thought how happy it would have been had all known the plain incestuous longing which his child so beautifully expressed in the first moment of this wonderful day. The splendid unification of life thus brought, the singleness of this pathology among all men, the directness of the path to light, gave him the exhilaration of a Salvation Army corporal. Little Paul had rolled his father into one of those side pockets which the literally minded describe as belief.

Now, what had happened to this man we may not pass by, for it is none too easy to understand what goes on as the wheel spins. When a man believes, he believes in something or somebody, and he ties himself up to this external thing or person. This is all plain. It is in the center. But back, something else has happened before this. It is much as if a resonance from the man's interior had been sounded. We all know of certain things which stir us, selective, personal things. But we all do not know that there is a kind of generic resonance which is not selective nor personal and which may be touched off a few times in our lives with a terrifying result which we call belief. And the gods have laughed through all the ages at the silly fuses which have loosed this, for is not this the peculiar mark of man? They see it really does not matter

what is this external thing which man believes; it may be a pulverized beetle or a prayer or a relic or a phrase or anything. They know that man really only believes in the resonance and only sees the external. He never has known of his resonance. If he had, history would have engrossed fewer halts when the cheering subsided. Paul's father believed in the incest. He had heard the word; he had seen the word in the act. This was the external and it was called incest and he thereby believed in incest. If it had been named mayhem, he would have believed in mayhem. And we must acquit him of not hearing the resonance. But we must hear the laughter of the Olympians, warning against the object of belief. This always is to be viewed with skepticism or suspicion. It is our right and privilege, then, to ask just what Paul's father did see, if he saw what he thought he saw.

This is what Paul's father saw really: He saw three people and three behaviors. The latter were as different, one from the other, as the former. They were made up of attitudes taken in relation to one another. It was not the intrapersonal background which he saw; even his own was quite vague. But he could see the relations between the different members in all this behavior of his wife, his child, and himself. It was these relations which he really saw. It was not the terms, his wife and child, and himself, but their behavior, which the relations showed or stood for. These relations presented between three social units. The context was social. Between mathematical entities such relations either show disparity, with one greater or less than the other, or equality. When the terms are social, there is always the disparity and never the equality. Man has always been greater or less than man, never equal to man. At the moment of Paul's entrance, the so-called dramatic element lay in the change of one set of terms between man and woman by which the father was replaced by the son. The tragedy lay in the peripeteia of the relation between man and man, for he who had been greater became less; the son took the place of the father. All that Æschylus felt was a fate which drove a son to excel the father. His genius lay in showing this relation in primitive pattern, but transferred to a later period where the same relation, emerging, horrified by its exposure of ill adjustment to life. It was the re-birth of the old, but only of the old relation in which the son became greater than the father. To the child the relation was a reality; to the man it was a fiction, out of correspondence with that reality to which society had made him adjust. Society punishes the fiction; calls it incest. In this she really criticises the terms, which are of sex. The young child carries no such terms, yet the Freudians name this also incest. Because the terms of man in adult years are sexual, then the terms in childhood are sexual, or, offending too grossly biology, psychosexual is given in place of sexual. Because a relation like Paul's is one of reality and a universal in childhood, therefore the later relation is of the same reality; that is, incest is a universal. They here have committed about all the logical errors possible. They only know something is common to both equations, to Paul and the adult Œdippus. Not being able to see it in the relations, they force the similarity or rather identity upon the terms.

Consider now what the Freudians have done to the terms and one can see how they have had to

blind themselves to the relations as the logical constant. The terms which enter into these relations are those of man in all his various activities. They are all we see or can see; they are the objective data, all these which we call behavior. The Freudians have denied all terms or activities but sex. All activity of life, all conduct, all behavior is sex conduct or behavior. Sex is the primary modality of life, and this sex enters in all relations. Now both these are at once assumptions and errors which have grown from a faulty method in the observation of the objective field of man's behavior. Yet it does display an attempt at scientific method. It has sought a constant as the physicist sought his in the concept of conservation or the chemist in his atom. But the constant here was sought in a term, whereas biology, dealing with life, finds it in a relation. The error was easier in that the term it assumed as basic, sex, has possessed earliest and in the most rudimentary form the singular facility of expressing the relation of disparity which is our constant. It is that instinct which has carried its tropismatic inevitableness furthest into consciousness and has grouped back of it the largest associative mass. But, equally certainly, it has been progressively dismissed as a term in the more highly evolved relations. The Freudians naïvely assure us that it enters into every later term, like a wandering and repressed Logos. Priority means to them paternity; that all other modes are born of this. To them life is not a continuum, a series of relations; but it is a succession of births in which an entire foundling asylum is filled by the same irresistible parent. They have been driven to this concept in their proper attempt at unification which wrongly seized upon a term instead of a relation as the constant. Just this far is it a "good little devil."

In emphasizing the relation as the constant in all the objective behavior of man one is isolating a definite objective manifestation in man. It is before the eye, the inequality of terms ever being perpetuated in its particular placement or reversed. Yet this is not a parent mode but a common mode in all relations. We disregard paternity when we emphasize its common quality. We do not need to assume it bore art and religion and science in the best Freudian manner; we only need see it objectively in art or religion or science as ultimate modes of behavior. Much less do we need to assure ourselves that Paul's desire to take his father's place in the mother's bed is incest, even in a "psychosexual" connotation. What we really observe is a disturbance in relations between father and son, in which the inferior son becomes the superior father. When we talk of this as incest, we are looking at terms. Yet the one thing we sense as familiar is the relational change. This is the old. We do not deny that incest, as we know it, is a return of this old, but cast in definite sexual terms. But we do insist that the terms here are but one mode of behavior objectively seen, while the Freudians insist that it is the only mode and make all other behavior derivative to it. To them all terms are sex; that is, all behavior is the objective data of sex. Seeking for a single source for all behavior, for the mother lode from which all conduct has slowly seeped its way outward, they have dug deep into early depositions of human life. One admits freely that a large mass of early material has been cast in sex terms. Then, all relations largely showed these terms. The lessened sex density of later stadia the Freudians have attempted, disas-

trously, to explain in civilization repressing the sex and substituting "sublimations," pallid cousins. But in missing the point of the relation being the constant rather than the term, they have missed that vision which sees this relation, not repressing but discarding the sex in seeking for wider, more plastic, more effective terms to express the movement from an inferiority to a supremacy. Because sex, as a term, is narrow, inelastic, and hence less fit for the more complex adjustments of society, it has been discarded. It has not been discarded as a term, but as a less useful term to carry the relation. It has not been repressed, as sex, but because it tended peculiarly to make the relation unbending and non-adaptive. Indeed, it is apparent that, until a wider range of terms were offered the relation, history was inarticulate. But it was the potentiality of the relation which drove man forward in the search. To seek for the power in the term is like studying dynamics in the Keeley perpetual motion motor. Behavior cannot be written except in relations.

History, as a study of behavior, has come to see a mutation of terms, but a constant of the fundamental motivation which the relation between the terms expresses. It acknowledges a revival of archaic terms, as sex, but in this always traces a reversion to a less plastic or flexible period, one in which the drive of the relation sought less vigorously to express itself. But it has not seen the increasing plasticity of civilization nor man's better social adjustments as the Freudian linear descendants of these archaic terms of sex. It refuses the formula of priority meaning paternity. History defines the increasing plasticity, expressed in more adaptive terms than sex, as arising solely from the demands of a more insistent relation disparity, which has thrown aside the old to seek the new.

We can study the individual in no different way. His behavior is in relation to others. The terms which the relation holds are varied and idiosyncratic. They constitute a part of what we call his trends. But the fundamental of his trends is the relational disparity which he discloses. The accretion of the associations are about the terms; but their potentiality and adjustment to society rest upon the constant, the relation which they develop in life. The one secure way to aid the adjustment is not to revive the terms, but to straighten out the relation which is wrongly adjusted. It is not Paul's incest with which he must be confronted; that would be to face him with terms. It is his non-adaptive supremacy over his father which he must be led to correct. He need not be laid within a bath of sex facts, anecdotes, and reminiscences that from their emanations he may arise revolted, disillusioned, and cured. But he must have the relation discovered to himself from every angle, that he may realize its non-adaptiveness. The richness and profusion of terms with which this single wrong relation comes to be seen in the vast field of affirmatory personal data are in striking contrast to the poverty of terms indicated by the painful and artificial elaboration to which the Freudian is driven. Thus has been made his Epic, which is neither Epic nor Incest.

It is plain that the criticism, here involved, is one of method. It is method upon which Freud's psychoanalysis in large part has been built. Upon this method the greatest security has been predicated. His concept of sex is well open to attack from the point of biology. That would stand as a

criticism of material selected for construction rather than as an evaluation of the method of construction. But such a criticism is secondary always to that applying to method and is only of corroborative value. If this criticism has been enclosed in a presentation which seems highly personified, it is hoped that the tinsel may be made to stand in the reader's mind as a vague reminder of the spectacular and popularized Freudian debuts which have issued out of that falseness and with that resultant artificiality which this paper has attempted to define as a fundamental error in method.

23 EAST SEVENTY-SEVENTH STREET.

FRONTAL AND MAXILLARY SINUSITIS AND SEQUELAE, DUE TO STAPHYLOCOCCUS PYOGENES ALBUS.*

BY RALPH OPDYKE, M.D.,

NEW YORK.

WE are all perfectly well aware that acute and chronic affections of the various sinuses are caused by streptococcic and the various staphylococcic microbes. Also that in some instances either of the above alone may be the exciting factor, but seldom do we find such a prolonged series of severe and obstinate involvements caused by the *Staphylococcus pyogenes albus* alone as in the case I report to-night.

W. W.; age 18; U. S.; single. Parents living and in good health; one older brother and no sisters. Has been affected with various ailments since childhood, all of which were of a serious character, among them being acute articular rheumatism when quite young, which left him with the usual mitral lesion which was aggravated by frequent succeeding rheumatic attacks. He had been a patient of mine for some years for minor attacks of tonsillitis and chronic pharyngitis. Just previous to this attack he had been preparing for college and doing extra chemical laboratory work which had lowered his vitality and resistance, a proof of which was the presence of a slight neurosis of his inferior maxilla, which healed only after several energetic curettings.

On Saturday morning, May 30, 1914, after dancing in his house and while still over-heated, he took home some of the house-party in his open car and caught a violent cold as a result of this exposure. On the following evening he was attacked with violent pain in and over his left eye, which was continuous and severe in character. His oculist examined him and reported nothing abnormal as to his visual fields. On the following noon and the third day of the attack, I was called to his home and found him suffering from an acute virulent maxillary sinusitis on the left side, with all the cardinal symptoms of the same—temperature 104.8°, pulse 118, respirations 18; he was thoroughly prostrated, in great pain, nauseated, extremities cold, and had all the symptoms of an acute suppuration.

On opening the antrum of Highmore with trocar an abundant amount of pus drained off, which on examination proved to be a pure culture of *Staphylococcus pyogenes albus*. It was found necessary to irrigate the antrum twice a day, as the amount of the discharge was very copious. Two days later the patient was taken with a severe attack of tonsillitis on the left side, with a quinsy resulting the following morning. It was necessary to lance not only the peritonsillar abscess but also to proceed through the posterior pillar and to the posterior pharyngeal wall in order to drain thoroughly the various pockets of pus. The discharge from it as well as from the antrum continued to be extremely free.

An autogenous vaccine was at once made from this culture and given at five-day intervals, without having any appreciable effect in staying the obstinate and persistent course of the disease. It was interesting to note a peculiarly marked exaggeration of the hip, knee, and ankle pains after each hypodermic dose of the vaccine, even though unusually small doses were given.

*Read at a meeting of the Section on Laryngology of the New York Academy of Medicine, October, 1915.

Several days later there appeared a marked swelling on the left side of the neck, anterior to the sternocleidomastoid muscle. Twenty-four hours later the condition became so serious and the patient so prostrated that an external operation became necessary. Dr. Abbe opened this abscess externally, with a free incision, inserting tubal drainage, and a direct connection was found to exist between the tonsil and the sinus, extending also well forward toward the arytenoids.

Following daily drainage, frequent gargling, and antrum irrigations, the patient improved constantly although his temperature and pulse kept up and he continued to have at times spasmodic pains in his left arm and right thigh, which seemed to be due to metastatic phenomena. Fearing a collection of pus in his right gluteal region where the pain was especially severe, aspirations were made in and about his right hip, with negative results, however. On June 6 he was able to be up and about for an hour at a time and was fairly free from pain; the drainage from the neck wound was scant, the neck wound partially healed, and the antrum practically well. The hip pains, though, continued to be very severe and were not controlled by antirheumatics nor analgesics.

On June 28, the patient complained of severe left frontal headache and his left frontal sinus was curetted. This treatment was continued as occasion warranted and with prompt relief to the patient. Even up to July 8 he continued running a temperature of from 100° to 102°, with a corresponding increase in pulse of from 110 to 124. His diet meanwhile was of a modified character with plenty of stimulation when necessary.

There seemed to be off and on a marked amount of photophobia and ocular distress, which at times was quite unbearable. On July 11 there appeared occipital headaches and insomnia, controlled only by morphine, the previously used hypnotics having failed to control his distress. On July 12, his left frontal sinus was again curetted and drained. An ice cap frequently applied to his occiput seemed also to give him some relief.

At no time previous to July 15 was there present more than a slight congestion in each visual field. From July 20 his temperature and pulse were not far above normal and he was able to be out of doors several hours each day, although the headaches continued to be somewhat more severe. On July 24, however, there were frequent attacks of nausea and several attacks of vomiting, the character of which material was not especially diagnostic.

On July 28, after probing his left frontal sinus and irrigating it, to my surprise, I removed a large piece of necrotic bone from his left nostril, which proved to be the major part of his left inferior turbinated bone which had gradually sloughed off. I might add that he had had present a very prominent nasal spur which during the previous violent nasal discharge had become adherent to the inferior turbinated bone, thereby interfering with drainage and forming a focus for the above referred to slough.

On July 31 an early and hasty summons to his bedside found the patient partially delirious, with a temperature of 104.4°, and complaining of cramps in his right leg, followed shortly afterward by a convulsion, epileptic in character. The clonic contractions of his right limb became very violent and uncontrollable; he frothed at the mouth with a tendency to bite his tongue; his left arm and left fingers twitched spasmodically, and his unconsciousness became complete; his pulse was thready and irregular, his extremities cold, his pupils equally dilated, and his color decidedly bad. Lumbar punctures revealed nothing. After the usual treatment in such a condition, heroically applied, he regained consciousness but remained in an exhausted condition, his temperature continuing to rise. The leg and arm symptoms moderated until they were more of a twitching character. At 11.00 A. M., four hours later, a similar attack was repeated, with all the earlier symptoms greatly exaggerated. Temperature was now 105°, pulse hardly perceptible, contractures most exaggerated, extremities icy cold, neck muscles rigid with head to the right, eyes wildly dilated with a double lateral nystagmus pointing to the left side, and absolute unconsciousness. His family physicians now believed him dying, and one of them even thought him dead. As a last resort, and extending little hope to his friends as to the outcome, I suggested an immediate decompression. They consented, and within forty-five minutes he was under the knife. Very little

anesthesia was necessary and a typical trephining was done over the fissure of Sylvius. Frequent aspirations through the dura into the parietal lobe revealed nothing, nor was the dura bulging nor discolored. However, on aspirating into the floor of the fourth ventricle there was drawn off about three drachms of seropurulent fluid which proved to be a pure culture of *Staphylococcus pyogenes albus*. The upper button of bone was replaced and a drain inserted in the lower space, and the usual semicircular flap reunited. The patient was put to bed and all emergency stimulative measures were carried out. His temperature, which had touched 106.8° previous to the operation, dropped to 104.8° two hours later.

He did not regain consciousness until early the following morning, his temperature staying about 104° F. There was no return of the convulsive seizures. Convalescence was naturally prolonged, the temperature and pulse slowly decreasing. For the first week frequent doses of morphine and hyoscine were necessary to control not only the limb and arm pains—which, though moderating, still existed—but also the extreme psychical condition of the patient. Frequent massage, alcohol rubbings, fluorescent rays, and sunshine aided to some extent his apparent return to health.

By August 9 his temperature had reached about normal, when unexpectedly he had a relapse, with a rise of temperature and pulse of marked degree and a return of most of his earlier epileptoid seizures.

After a hasty consultation it was decided that a second decompression was necessary. The patient was quickly prepared for operation, anesthetized, and an extensive operation was completed in fifty minutes. At this time the replaced button which had become adherent to the dura was taken out, and the parietal, occipital, and temporal bones were resected to a considerable extent.

The resulting uncovered dural area was about 3½ inches in diameter. The dura was cut crucially, and the hemisphere again explored in all directions, with a negative result, save that, as before, some fluid was aspirated from the floor of the fourth ventricle. In this instance, only about thirty minims were withdrawn. The lateral sinus was exposed from about the knee well back toward the occiput, and appeared healthy in color, as well as being freely compressible. The dura was not reunited, and the inverted horseshoe flap was returned and sutured, with a small cigarette drain inserted at its inferior angle. The patient rallied nicely and, as before, the exciting constitutional and local symptoms slowly subsided.

The convalescence in this instance was highly satisfactory in every way, and at the time of the removal of the sutures and wick, four days later, his temperature and pulse had become nearly normal. By August 15 he was able to eat squab, and a few days later he was strong enough to be in a Morris chair for a short time.

Unfortunately, a hot water bag had severely burned the crest of the left ilium after the second operation, and for several weeks the series of nasty burns of the first and second degree were obstinate in healing.

It is interesting to note that neither before nor after this second attack and the above-described operation were the various lumbar punctures positive.

On August 14 frontal pains of a violent character started up out of a clear sky, and nothing given locally or constitutionally eased them at all. An immediate double radical frontal operation was insisted upon, which was approved and acquiesced in. This was at once done, and the findings were as follows: Right frontal sinus—a noticeably small sinus above its nasal opening, the surrounding bones being extremely eburnated, and the mucous membrane lining this embryonic cavity slightly necrotic. Left frontal—enormous in size, filled with necrotic detritus, and with a distinctly foul odor. This left sinus was thoroughly curetted, the nasal opening enlarged, the punctate necrotic bony areas cauterized, and the skin sutured with fine silk—with perfect primary union and no visible cicatrix later.

In twenty-four hours his temperature dropped from 104° F. to normal, and remained there. His convalescence was subsequently rapid and, following the administration of the proper tonics and systemic treatment, he gradually recovered his strength, color, weight, and general health.

It goes without saying that during and after the numerous and terrible attacks his strength and resistance had become of the lowest character, and he

was a skeleton as to weight, a ghost as to color, and as pitiable an object as one is wont to see. However, throughout it all, save in his moments of unconsciousness, he was mentally most alert and keen as to his subjective symptoms, and helpful to us all in the handling of his case.

A rest at the seashore in the fall and a vacation during the winter have restored completely the patient who, at the time of this writing, weighs about 170 pounds and is apparently in perfect health.

He wears, when liable to injury to his head, a metal plate made from a plaster cast, in such fashion as to protect perfectly the area left without a skull covering.

In March, 1915, he had a violent attack of quinsy on the same left side, and it appeared for a time as though the above history might be repeated, but fortunately he recovered after many thorough lancements of the peritonsillar area. In this recent attack the culture was mixed *Staphylococcus pyogenes albus* and streptococci, the latter being in the great minority.

It is pleasant to report that there exists at this time no observable scar about his head designating the line of incision of the many operations I performed on him. This summer his tonsils were enucleated, and he is at the present time enjoying perfect health.

It has seemed to me that this case, continuing over so many months, with its many marked and constitutionally dangerous symptoms, following the usually more or less harmless infectious microbe—the *Staphylococcus pyogenes albus*—with its numerous operations (twenty-one in all), with its sure but delayed recoveries, and its final fortunate outcome, is one well deserving of a complete report.

40 EAST FORTY-FIRST STREET.

Medicolegal Notes.

Consent to Method of Operation.—Action for damages was brought against a surgeon for trespass to the plaintiff's person in removing an ovarian tumor by what was alleged to be an entirely different operation from the one authorized by the plaintiff. The tumor was removed through an incision made in the skin immediately between the external opening of the genitals and the bowels, or what the plaintiff called the "lower or rectal operation." She claimed that she consented to an operation by an incision through the walls of the abdomen, but not to the lower or rectal operation. The evidence showed that the operation was performed in the manner outlined in a letter by the surgeon to the plaintiff's family physician, which she had received, without any objection by her. The surgeon was without knowledge that she had objected to any one to the operation as outlined by him in his letter. It was held that the plaintiff could not recover.—Gould vs. Kerlin, 192 Ill. App. 427.

Sale of Cocaine—Ignorance of Violation and Intent.—Action was brought to recover penalties for sales of cocaine made by a wholesale physicians' supply house to a person in violation of an ordinance of the City of Chicago prohibiting sales of such drug to a person addicted to the habitual use of morphine and cocaine, and without a written order of a duly registered practising physician when made at wholesale. The buyer of the drug was a licensed, but not a practising physician, and had no office and no patients. It was held that it was no defense that the defendant's clerk who made the sale had previously dealt with the purchaser as a practising physician, and had no knowledge of his habits; but proof of the intent or ignorance of the person making the sale is admissible for the consideration of the jury in determining the amount of the penalty. The evil intended to be abated requires the strictest police regulation and it was held to be no objection to such rigid enforcement of the ordinance that the extreme precaution required to escape the penalty of its violation may in some instances impose hardships.—Chicago vs. Truax Greene & Co., 192 Ill. App. 524.

Opinion Evidence as to Probably Supervening Paralysis.—The Illinois Appellate Court holds that the opinion of a physician that the plaintiff in an action for personal injuries was "liable" to have recurrent attacks of paralysis and that the degenerative state of the nerve tissue and

its surrounding connective tissues might lead to developments that are liable to bring about a paralytic stock are objectionable. The statement of a mere probability of the recurrence is not sufficient. Where the subject matter of the inquiry was whether paralysis, if produced by an injury, would necessarily follow almost immediately, and also whether or not an injury such as the plaintiff claimed to have sustained was capable of producing paralysis, it was held competent for a medical witness to express his opinion thereon and to state his reasons for such opinion.—Hutchison vs. Chicago City Ry. Co., 192 Ill. App. 464.

Malpractice—Professional Skill, etc., Questions for Experts.—The Michigan Supreme Court holds that in an action against a physician or surgeon, matters of special knowledge strictly involving professional skill and attention, unskillfulness, negligence, or failure to do that which ought to be done, must be shown by the testimony of those learned in such matters, and the jury cannot be permitted to draw their conclusions from their own unprofessional notions as to proper treatment. In an action against a surgeon for performing operations on the plaintiff more serious than those she understood were to be performed, in which it was also claimed that a hernia resulted from one of the operations, no physician or surgeon questioned the propriety of the operations, or the care and treatment given the plaintiff by the defendant, or expressed the opinion that the hernia was attributable to want of skill or negligence, while surgeons did testify that the operations were necessary and properly performed, and that hernia resulted where there were no operations, and were no evidence of malpractice or unskillfulness. It was held that there was no question for the jury as to negligence or unskillfulness, and the court properly submitted only the question of whether the plaintiff understandingly submitted to the operation; on which question the jury found for the defendant.—Zotterell vs. Repp, Michigan Supreme Court, 153 N. W. 692.

Cystitis Alleged from Use of Dirty Catheter—Insufficient Proof.—In an action against a hospital the plaintiff contended that she contracted cystitis by the negligent use by a nurse of an unclean catheter. There was no evidence that the catheter used was unclean, and the opinion of a physician, called by the plaintiff, that in his opinion her trouble was caused by the use of a dirty catheter was not founded on any evidence in the case, and was the naked conclusion of the witness. Cystitis, the court said, does not necessarily follow from the use of a catheter, and no inference could be indulged in the case at bar that its use was the cause of the plaintiff's infection, or that it was unclean and not in proper condition for use.—Moses vs. St. Barnabas Hospital, Minnesota Supreme Court, 153 N. W. 128.

Action for Services—Lack of Value as a Defense.—In an action by a physician to recover for medical services to the defendant's minor child, who was injured in an accident, the defendant's family physician, who was called into consultation with the plaintiff at the defendant's request, testified that the child's condition indicated that death was imminent, that the plaintiff admitted having reached the end of his medical resources, whereupon he suggested to the plaintiff the injection of a saline solution, immediately after which the child's condition improved, and that if the injection had been made earlier it would not have been necessary to remove as much of the child's leg as was afterward amputated. The Illinois Appellate Court held that the testimony was admissible as having a tendency to raise an issue of fact as to whether the plaintiff's services were of any value, and that proof that such services were of no value was a defense to the action.—De Tarnowsky vs. Walker, 191 Ill. App. 610.

Physician and Patient—Privileged Communications.—The Missouri Supreme Court holds that communications by a party suing for a personal injury to a physician examining him under order of court directing him to submit to a physical examination by the physician, are not privileged communications within the Missouri statute. The injury was received nearly three years before the trial. The plaintiff testified that he had been afflicted with gonorrhea, and that a stricture, which might have been the cause of the injury complained of, had only been present two years. It was held that the testimony of the physician appointed by the court to examine the plaintiff, that the latter made statements in conflict with his testimony, was admissible to impeach the plaintiff, in the absence of anything to show that the statements to the physician were not voluntary.—McGuire vs. Chicago & A. R. Co. (Mo.) 178 S. W. 79.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery

New York, January 1, 1916.

FREQUENCY OF RECURRENCE OF STONE IN THE KIDNEY AND URETER AFTER OPERATION.

It is now 35 years since Henry Morris did the first nephrotomy for the removal of a calculus from an otherwise supposedly healthy kidney, and the same length of time has elapsed since Czerny removed a pelvic stone by pyelotomy. These 35 years have seen remarkable advances in the field of renal surgery due, in a large measure, to the recent rapid development of *x*-ray and cystoscopic technique. With such marked progress in almost everything pertaining to renal surgery, it is hard to understand why the frequency of recurrence of stone after operation remained so long undetermined; particularly since in recent years the propensity for statistical studies has been rampant. Consequently, one is hardly prepared for Cabot's amazing statement that he could find no useful statistics bearing upon this important subject. One explanation of this statistical hiatus advanced by H. Cabot and Crabtree (*Surgery, Gynecology and Obstetrics*, August, 1915) is that it is in only comparatively recent times that a diagnosis of recurrent stone could be made with accuracy. Another explanation, which we would suggest is that surgeons have been unaware of the late recurrence of stone since patients very soon pass from their charge to that of the family physician and also because here, as in gall-bladder cases, both patient and family physician have often considered that the recurrence of symptoms pointed to a stone which the operator had carelessly overlooked, hence the patient goes to another surgeon for the secondary operation.

Be that as it may, it has generally been considered that when but one kidney was involved recurrence after operation was unusual in aseptic cases and far from frequent in the presence of renal infection. That this conception of the matter is far from correct has been shown most conclusively by Cabot and Crabtree, whose paper is based upon a study of 155 cases operated upon for stone in the kidney or ureter by various surgeons at the Massachusetts General Hospital during the eight years previous to January 1, 1914. They feel that the results of their study may be considered to represent a fair average of those obtained throughout the country. Of the 155 cases, but 87 could be satisfactorily

studied; for the authors insisted that all patients should come to them so that a careful physical examination, an examination of the urine, and an *x*-ray could be made. Upon nothing less than this were they willing to report end-results. They recorded as cured those patients who presented a negative physical examination as far as the urinary tract was concerned, who had a normal urine on chemical and microscopical examination, and in whom the *x*-ray was negative. They recognized the fact that even with the urine normal and the *x*-ray negative it is possible that stone may be present; but they considered it would be so unusual for a stone to go undetected, if present, under the conditions stated above that they could safely disregard such a possibility.

Of the 87 cases, 66 had been cases of stone in the kidney and 21 of stone in the ureter. Of the 66 cases of stone in the kidney, 34, or 51 per cent., were well and 32, or 49 per cent., were not. Of the 21 cases of stone in the ureter 15, or 71 per cent., were well and 6, or 29 per cent., were not. They now attempted to determine whether or not the type of operation was an important factor in the result, and found that of 30 cases treated by nephrotomy, 13, or 43 per cent., were well and 17, or 56 per cent., were not; of 33 cases treated by pyelotomy, 16, or 49 per cent., were well and 17, or 51 per cent., were not; and of 12 cases treated by nephrectomy, 11, or 92 per cent., were well and 1, or 8 per cent., were not. The authors explain that in referring to the cases of nephrectomy as well or not well, they refer to the patient rather than to the kidney. It is interesting to note that in only one case did stone form in the remaining kidney.

Cabot and Crabtree do not find infection a factor of great importance in the recurrent formation of stone: nor did the length of time that the original stone had been in the kidney seem to have any bearing on recurrence; for of 8 cases with a history of less than one year, 4 cases recurred and 4 did not; of 14 cases of six years' duration, 4 recurred and 10 did not; of 6 cases of fifteen years' duration, 4 recurred and 2 did not; and of 6 cases of twenty years' standing, 3 recurred and 3 did not. Regarding the influence of age, they found that in patients of less than 35 the probability of recurrence is comparatively large, while when the age is over 40 it is comparatively small.

In summing up the situation the authors say: "It appears that we shall have to revise somewhat our rather optimistic views as to the results of operation for stone in the kidney. * * * Most of us have, I think, been in the habit of assuring the patient that the probability of cure is large. On the basis of these cases we can only say to the patient that the risk of operation is small; that the danger of progressive destruction of the kidney by the stone, if it is left, is large; that the probability of recurrence is considerable; that it depends somewhat upon the age, undoubtedly somewhat upon the method of operation and the skill with which it is carried out, but clearly somewhat upon the entirely unknown factor—the liability or the ability of that particular kidney to form concretions. The outlook for the cases of stone in the ureter is apparently

considerably better. In this small series of 21 cases the probability of permanent cure seems to about two to one."

Undoubtedly we shall have to revise our ideas in regard to the recurrence of stone after operation. While it is possible and, indeed, we think probable that the study of a larger series of cases may lower this actually appalling ratio of failures to cures, it is certain that we have been far too optimistic heretofore and that conservatism must be the watchword in prognosis hereafter.

DISEASE FACTORS IN THE DEVELOPMENT OF TUBERCULOSIS.

APART from the fact of the inherent virulence of the tubercle bacillus, its almost universal distribution among the human races, and its tendency to cause an hereditary predisposition, although it is not itself thus transmitted, there are a number of disease entities which seem to prepare the system for the easier invasion. Or, it may be that the tubercle bacillus flourishes better in symbiotic relation with the bacterial agents causing the other morbid conditions. While the campaign of education in respect to the prophylactic measures necessary in the eradication of foci of infection has been of great value, the advances in epidemiological knowledge and control has perhaps been of even greater value. And yet the morbidity tables from such diseases as measles, whooping cough, and influenza, diseases eminently predisposing to the development of tuberculosis, are still large despite the ever-increasing efficiency and vigilance of the health authorities. Indeed, so much of the tuberculosis incidence has its origin directly in one of these diseases that a large part of the campaign against tuberculosis can with profit be launched in this direction. The public is very gradually being weaned from the superstition that every child must contract measles, that the sooner over with the better, and that healthy children should be exposed to the disease on the first opportunity. Some physicians even, while not flat-footedly approving this notion, do not interpose very serious objection to it. They realize, indeed, the dangers to life from complicating bronchopneumonia though oblivious to the larger, though not so immediate, danger from tuberculosis.

That the recent epidemic waves of influenza have played a very pertinent part in keeping the tuberculous population still rather high is universally conceded by the medical profession although the laity do not yet seem to understand even the inherent gravity of this disease. Many fulminant types of tuberculosis are, nevertheless, traceable to this disease. Until the public learns the true significance of the disease the quarantine regulations must be perhaps more strict than for other quarantinable diseases. Of the non-specific conditions figuring in the development of tuberculosis may be mentioned tonsillar disease. Because of the wide distribution of gland tuberculosis its benign nature has often received comment. It was even the belief at one time that

gland tuberculosis immunized against further infection. Certainly, its wide distribution and its amenability to cure well illustrate Virchow's contention that there is no one who does not at one time or other have a tuberculous infection, but that most individuals easily overcome it. He found cured tuberculous nodules in the lungs of nearly all bodies coming to autopsy for other than this disease. Infection with tuberculosis alone seems to be self-limiting. But in conjunction with other bacterial agents the tubercle bacillus assumes an extreme virulence.

Diabetic patients and those with cirrhosis of the liver seem to have an especial predisposition to infection with tubercle bacilli. In both instances the complicating tuberculosis appears late in life, and though ordinarily later-life tuberculosis is of slower course and more benign in nature, it is here particularly fulminant. This proneness to tuberculosis existing in cirrhosis of the liver illustrates the erroneous impression long existing that alcoholic indulgence of a high degree—which so often is the cause of the cirrhotic condition—will cure tuberculosis. On the contrary, alcohol is a direct as well as an indirect predisposing factor in this disease.

THE FEVER THERAPY OF GONORRHEA.

IT has long been known that the gonococcus cannot survive in a temperature of 42° C. (108° F.). Even at 39° or 40° (102°-104° F.) proliferation becomes notably inhibited. In gonorrheal patients who chance to develop high fever, secretion becomes arrested. Nevertheless in practice ordinary hot air and diathermy seem to exert no decided action on the disease, probably because the entire blood mass should be heated at once.

In the *Münchener medizinische Wochenschrift* for November 2, Dr. Weiss relates his attempts to raise the temperature of the entire body to the theoretically indicated point. His gonorrheal patients were placed in hot baths of from 40° to 43.5° C. (104°-110° F.) and their temperature was increased from normal to as high as 42.6° (105° F.). The tolerance to these temperatures was very variable. It was of course to be thought of that such temperatures might also weaken the natural immunity of the tissues. The bath was of the vapor type, and the head was protected by an ice-bag. One patient received a bath of 40 minutes and his highest temperature was 42.6°. His discharge, which was purulent and full of gonococci, became very slight and sterile. In another case the same results were obtained with a shorter bath and lower temperature. A third underwent two baths before recovery. In the first his temperature did not rise above 39.7° and cocci were still present in the discharge. A second bath brought about a temperature of 40.3°, which appeared to destroy all cocci. In patients not cured after one bath, in addition to more baths permanganate of potassium injections were given. Generally speaking, Weiss says, when the first bath can raise the body temperature to 42.6° a brilliant recovery may be anticipated. Six patients, despite ideal external conditions, could

not be made to react to a point high enough to kill the cocci. This failure seems due to circulatory conditions. It must not be forgotten that—as is noted in the case of the ordinary vapor bath—many individuals cannot with safety make use of them. The thoracic organs must always be examined before one ventures on these baths. Collapse occurs in some subjects and the bath must be discontinued as soon as the patient begins to feel uncomfortable.

THE DANGERS OF SACCHARINE.

WHILE it is fortunate that we have such an acceptable substitute, from a gastronomic point of view at least, for sugar as saccharine, still we must not close our eyes to its dangers. Certainly it should not be placed in the hands of a diabetic who will have to use it over long periods of time, perhaps the rest of his life, without some reservations or qualifications. It should be remembered that while sugar is a food saccharine is only a chemical substance which happens to have for one of its properties an extremely sweet taste. Derived as it is from coal-tar, it would be surprising indeed if it did not possess somewhere some drawback or undesirable quality, for all the members of this family seem to have one pet failing or another. Saccharine has been accused of being instrumental in causing certain forms of cancer, the so-called pitch or tar cancer. Of course, nearly everything in the earth, sea, and sky has been accused at one time or another of producing cancer, but the evidence against saccharine of being at least a predisposing cause of certain forms of epithelioma is sufficiently weighty to make us avoid taking the risk of using it except through compulsion. Be it innocent or guilty in the cancer matter, at least we know that it is a chronic irritant to the gastrointestinal tract, particularly to the stomach; that much has been demonstrated beyond cavil by the Department of Agriculture in 1911 and published as Report No. 94. Taken internally over long periods or in excessive doses it causes various digestive disturbances, prominent among which are hyperchlorhydria and nausea. In fact any dose over five grains may be considered unsafe. We are certainly not justified then in the somewhat complacent attitude assumed by some members of the profession toward this drug, but should issue it to diabetics with the same caution and admonitions with which we would accompany the giving of any other powerful medicine.

CONVALESCENT SERUM IN TREATMENT OF MEASLES.

IN the course of a severe epidemic of measles in Ancona during the latter half of 1914, Umberto Majoli (*Il Policlinico* September, 1915), essayed this method of treatment. It consists in the use of the blood serum of patients convalescent from measles in the treatment of other patients in the acute stage of this disease. This mode of therapy has never been tried before in measles, although convalescent serum has been used for some time in scarlet fever—by Weissbecker in 1896, by von Leyden, Huber, and Rosenthal in 1902, by E. Reiss

and P. Jungmann in 1912, by R. Koch in 1913, and by Zingher in 1914. Majoli removed by venesection 250 cubic centimeters of blood from the convalescent patient in whom a negative Wassermann reaction had already been demonstrated. The serum was kept at low temperature for 24 hours and then transferred to sterile vials of 5 to 10 cubic centimeters capacity. In the treatment there were used according to the severity of the case daily injections of 5 to 20 cubic centimeters. The mixed serum obtained from several convalescents produced apparently better results than the serum obtained from one individual. The good effects attributed to this method of treatment are the lowering of the temperature throughout the entire course of the disease, the shortening of this course, and the absence of complications.

News of the Week.

Committee of American Physicians for the Relief of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7018 Jenkins Arcade Building, Pittsburgh, announces the receipt of the following contributions for the two weeks ending December 25:

Mr. Jos J. S.	\$2.00
Receiv. on Mr. J. S.	1.00
Receipts for the two weeks ending December 25....	\$27.00
Previously reported receipts.....	7,903.86
Total for the two weeks ending December 25.....	\$7,930.86
Previously reported receipts.....	1,625
1,625 Standard boxes of food at \$2.20....	\$3,575.00
1,274 Standard boxes of food at \$2.30....	2,930.20
353 Standard boxes of food at \$2.20....	776.60
Total for the two weeks ending December 25.....	7,310.04
Balance	\$620.82

War Death Rate Drops.—Official statements recently made show a remarkable decrease in the death rate of wounded and sick soldiers in both the German and the French armies. For the German army the statistics show that while in the first months of the war 3 per cent. of the wounded and sick soldiers died, 12 per cent. were discharged, and 85 per cent. returned to active service, the death rate since then has fallen steadily until now the monthly average is 1.7 per cent., the discharges average 8.8 per cent., and 89.5 per cent. are still fit for service. For the French army the official statistics give the mortality among the sick and wounded soldiers in the war hospitals during the month of September, 1914, as 45 per 1,000, and during the past months as only 18 per 1,000. In peace times, the report states, the hospitals of Paris show a mortality rate of 106 per 1,000.

Decrease in National Mortality.—The United States Census Bureau estimates that the death rate for 1914 in the registration area of the country was 13.6 per 1,000 of population, and states that this is the lowest rate on record for the United States. The returns cover about 67 per cent. of the population and are considered trustworthy. Some surprising reductions in the death rates of various cities and parts of the country are shown; thus, the death rate of New York City has fallen 25.8 per cent.; that of Jersey City, 28.5 per cent.; of Newark, 22.5 per cent.; of Paterson, 20.1 per cent.; of San Francisco, 23.6 per cent.; of Denver, 23.3 per cent., and of Pittsburgh, 21.9 per cent. Among the States, New York shows a reduction of 14 per cent.; New Jersey, 11.8; Massachusetts, 11.4; Connecticut, 3.8; Rhode Island,

17.4; Vermont, 7.4, and Maine, 1.9. Michigan alone shows an increase, amounting to 0.8 per cent. only.

Health of the Canal Zone.—The Chief Health Officer of the Panama Canal reports that during the month of October, 1915, one case of yellow fever was received at quarantine; the patient was admitted to the Ancon Hospital and died the following day. With this exception, no cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month. Among employees, numbering 33,419, the total number of deaths from all causes was 20, of which 15 were due to disease, giving a death rate from disease of 5.39 per 1,000 as compared with 4.82 for the preceding month and 4.68 for the corresponding month of last year. The total number of admissions to hospitals and quarters was 821, a rate of 294.8 per 1,000, as compared with 307.34 for the preceding month, and 344.23 for the corresponding month of last year. This is the lowest rate ever attained at this season of the year. Among the population of the Canal Zone, amounting to 30,219, there was 39 deaths, 33 of which were due to disease, giving a death rate of 13.10 per 1,000. The reported births numbered 64, 19 white and 45 colored; and there were 11 deaths of children under 1 year of age. In Panama City, with a population of 60,373, there were 135 deaths from disease, a rate of 26.83 per 1,000, and 206 births; while in Colon, with a population of 29,331, the deaths numbered 56, a rate of 22.91 per 1,000, and the births 56. The general work of sanitation was carried on as usual.

Police Psycopathic Laboratory.—After preliminary experimental work extending over two months, the Police Commissioner of New York has established a laboratory for the purpose of examining prisoners so as to determine which among them are mentally defective. The laboratory will be situated at Police Headquarters and will be well equipped for the work. It will be under the direction of Dr. Louis Bisch of New York, who has also conducted the experimental work.

Dr. Witthaus' Estate.—By the will of the late Dr. Rudolph A. Witthaus, whose death was announced last week, the New York Academy of Medicine receives the bulk of his estate, amounting to upwards of \$100,000, the income to be used for the benefit of the library. Dr. Witthaus also left all of his books to the library of the Academy, and expressed the wish that it might be made more accessible to readers than in the past, especially on Sundays. Under a new rule, established after this will was written, the Academy library is regularly open to members on Sundays and holidays.

Another Centenarian.—Thomas Dowling of Nyack, N. Y., said to have been the oldest man in Rockland County, died on December 20, at the age of 104 years.

To Allow Horse Meat.—The Board of Health of New York City on December 21 passed an amendment to the Sanitary Code permitting the slaughtering of horses and the sale of the flesh as food. The measure goes into effect on January 1, and revokes a prohibition which has been in force since New York became a city.

American College of Surgeons.—The American College of Surgeons announces that it has secured from its Fellows an endowment fund of \$500,000, the money to be held in perpetuity, and the income only to be used to advance the purposes of

the college. The college now lists about 3,400 fellows in Canada and the United States, and is a powerful factor in the development of the art and economics of surgery. Its purposes are concerned directly with matters of character and of training, with the betterment of hospitals and of the teaching facilities of medical schools, with laws which relate to medical practice and privilege. The raising of this endowment fund assures the progress of the college towards its ideals along a number of lines of activity which have been mapped out for it.

Work for the Blind.—The New York State Commission for the Blind has issued a list of blind persons engaged in various trades and occupations, including basket makers, broom makers, chair caners, dictaphone operators, singers, masseurs, rug makers, piano tuners, printers, etc. This list will be supplied on application to the Commission at 105 West Fortieth street, New York.

Civil Service Examinations.—The New York State Civil Service Commission announces an examination on January 22, 1916, for the purpose of filling vacancies in the following positions:

Assistant physician, regular, in State Hospital and in various State and county institutions. Salary in State Hospitals, \$1,200, increasing \$100 each year to \$1,600, with maintenance, including quarters, board, laundry etc. The examination is open to men and women who are licensed medical practitioners in this State who have graduated from a registered medical school, and who since graduation have had one year's experience on the resident medical staff of a general hospital, or as medical interne or clinical assistant in a State hospital or institution, or have been engaged for three consecutive years in the practice of medicine.

Laboratory assistant in bacteriology, State Department of Health. Candidates, either men or women, who have satisfactorily completed a systematic course in bacteriology and have also had not less than three months' practical experience in laboratory work, will be admitted to the examination.

Application blanks will be furnished before January 10 by the State Civil Service Commission, Albany, N. Y.

United States Public Health Service.—An examination of candidates for admission to the grade of assistant surgeon in the United States Public Health Service will be held on January 24, 1916. Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and of good professional and moral character, with at least one year's hospital or two years' professional work. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order. They will receive early appointments. After four years' service assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon, and after twelve years to the grade of surgeon. Assistant surgeons receive \$2,000, passed assistant surgeons, \$2,400; surgeons, \$3,000; senior surgeons, \$3,500, and assistant surgeon generals, \$4,000 a year. For invitation to appear before the board of examiners' application should be made to "Surgeon General, Public Health Service, Washington, D. C."

A New Journal.—The first issue of the *Journal of Cancer Research*, the official organ of the Ameri-

can Association for Cancer Research, is announced for January, 1916. Dr. Richard Weil of New York is the managing editor of the new journal, and he will be assisted by an editorial committee composed of members of the association. The journal will be issued quarterly.

To Aid Mexico.—Because of the reported prevalence of typhus fever in Mexico, Secretary of State Lansing has made inquiries of General Carranza as to whether he will not lift the ban against the American Red Cross in Mexico and permit it, in conjunction with the Rockefeller Foundation to undertake the task of stamping out the epidemic. The Red Cross last fall gave up its relief work in Mexico at the request of General Carranza, who stated that the Mexicans themselves were able to handle the situation at that time.

Quarantined in Hospital.—The staff and the patients, numbering about 150, of the Cumberland Hospital, Brooklyn, are all under quarantine in that institution because of an outbreak of diphtheria. Three of the physicians on the staff have contracted the disease.

Wood Alcohol Inquiry.—The Department of Health of New York has requested the office of the District Attorney of Kings County to investigate the use of wood alcohol in Brooklyn. The deaths of two workmen and the blinding of a third, all of whom were employed as varnishers in a brewery in that city, have called attention anew to the dangers of wood alcohol and to the fact that it is so often mislabelled and improperly sold.

Leeuwenhoek Medal.—The Leeuwenhoek gold medal of the Royal Academy of Sciences of Amsterdam has recently been awarded to Surgeon General Sir David Bruce of the British Army for his work in parasitology. This medal is awarded every ten years in recognition of the most remarkable observations made during the decade on the microscopical organisms first discovered by Leeuwenhoek in 1675. The medal was presented to Sir David Bruce at a meeting of the Academy in Amsterdam on December 18.

Aid for State Hospitals.—At a conference on the budget for the New York State Hospitals, held in Albany on December 20, Governor Whitman approved requests for new construction and permanent betterment work at the various hospitals to the amount of \$1,042,493. The Governor announced a plan to relieve the present overcrowding in the State institutions by the use of the \$300,000 unexpended balance of the appropriation for the Mohansic Hospital to defray part of the cost of the construction and equipment of a hospital building to be devoted solely to the care of old and feeble persons, most of them victims of senile, dementia, now inmates of the State hospitals. A building to house 2,000 patients at least has already been planned, and it is proposed that the Legislature be asked to appropriate \$700,000 so that it may shortly be erected, preferably on the grounds of the Middletown State Hospital, a site which has been chosen because of its accessibility to New York, whence more than half of the patients in the State hospitals are drawn. The use of such a building would very nearly do away with the overcrowding.

Medical Society Elections.—**BROOKLYN NEUROLOGICAL SOCIETY.** The following officers were elected at the annual meeting of this society recently: *President*, Dr. Siegfried Block; *Vice-President*, Dr. C. P. Frischbier; *Secretary-Treasurer*, Dr. C. P. Meagher.

TULSA (OKLA.) ACADEMY OF MEDICINE. This was organized at a meeting of the medical profession of Tulsa held on October 28, 1915, the following officers being chosen: *President*, Dr. W. Forest Dutton; *Vice-President*, Dr. R. S. Wagner; *Secretary-Treasurer*, Dr. Paul N. Atkins.

SOMERVILLE (MASS.) MEDICAL SOCIETY.—At the annual meeting held on December 2 in Somerville, the following officers were elected: *President*, Dr. F. E. Bateman; *Vice-President*, Dr. F. N. Stephens; *Secretary-Treasurer*, Dr. E. F. Sewall. Dr. Charles A. Porter of Boston was the guest of honor.

ST. LOUIS (MO.) MEDICAL SOCIETY.—The following officers were elected at a meeting held on November 27: *President*, Dr. L. C. Boisliniere; *First Vice-President*, Dr. Walter Baumgartner; *Second Vice-President*, Dr. W. H. Stauffer; *Secretary*, Dr. J. A. Seabold.

SOMERSET COUNTY (ME.) MEDICAL SOCIETY.—The annual meeting of this association was held in Skowhegan on December 2, officers being elected as follows: *President*, Dr. R. C. Brown, Bingham; *Vice-President*, Dr. J. A. Thibodeau, Madison; *Secretary*, Dr. H. W. Smith, Norridgewock.

THIRD DISTRICT (GA.) MEDICAL ASSOCIATION. At the annual meeting held in Americus on November 17, the following officers were elected: *President*, Dr. W. H. Prather, Americus; *Vice-President*, Dr. Louis Grubbs, Americus; *Secretary-Treasurer*, Dr. Charles A. Greer.

AMERICAN ASSOCIATION OF CLINICAL RESEARCH.—At the annual meeting held recently in Philadelphia the following officers were elected: *President*, Dr. Warren Coleman, New York; *vice-presidents*, Dr. William B. Snow, New York, and Dr. Leon T. Ashcraft, Philadelphia. Dr. James Kraus, Boston, is permanent secretary.

ELEVENTH DISTRICT (GA.) MEDICAL ASSOCIATION.—The following officers were elected at the annual meeting held on December 3: *President*, Dr. B. H. Minchew, Waycross; *vice-president*, Dr. Quitman Holton, Douglas; *secretary*, Dr. J. W. Simmons, Brunswick; *councillor*, Dr. C. L. Drew, Willacoochee.

KENT COUNTY (R. I.) MEDICAL SOCIETY.—At the annual meeting held on December 9 at Arctic, the following officers were chosen: *President*, Dr. P. C. Means, Apponaug; *vice-president*, Dr. C. L. Phillips, East Greenwich; *secretary*, Dr. H. B. Bryer, Natick; *treasurer*, Dr. F. B. Smith, Washington.

NORTH CENTRAL ILLINOIS MEDICAL ASSOCIATION.—At the second annual meeting held in Peoria on December 8, officers for the ensuing year were elected as follows: *President*, Dr. James A. Marshall, Pontiac; *vice-presidents*, Dr. F. W. Wilcox, Minonk, and Dr. David S. Conley, Streator; *secretary-treasurer*, Dr. George A. Dicus, Streator.

BALTIMORE CITY (MD.) MEDICAL SOCIETY.—The following officers were elected at the annual meeting on December 1: *President*, Dr. C. Hampson Jones; *vice-president*, Dr. F. H. Baetjer; *secretary*, Dr. Emil Novak; *treasurer*, Dr. W. S. Gardner.

Obituary Notes.—Dr. HERMAN PETER GERBERT of Orange, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1883, died suddenly at his home, from heart disease on December 19 aged 57 years.

Dr. JEREMIAH ELWOOD SAYRE of Red Bank, N. J., a graduate of the Jefferson Medical College, Philadelphia, in 1883, died at his home on December 11, aged 63 years.

Dr. RODERICK FRASER, formerly of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1897, an alumnus of the Lying-In Hospital, formerly physician to the Bloomingdale Clinic, and a member of the American Medical Association, the New York State and County Medical Societies, and the West Side Clinical Society, died at Saranac Lake, N. Y., after a long illness, on December 13, aged 45 years.

Dr. CHARLES A. HAFFNER of New York, a graduate of the College of Physicians and Surgeons, New York, in 1896, assistant physician at the Roosevelt Hospital Dispensary, and a member of the New York State and County Medical Societies, the West Side Clinical Society, and the West End Medical Society, died at his home on December 14, aged 39 years.

Dr. WILLIAM EPAPHRODITUS THOMAS of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1895, died at the German Hospital, Brooklyn, from pneumonia on December 14, aged 42 years.

Dr. GEORGE PEARSLEE SHEARS of New York, a graduate of the New York University Medical College in 1886, clinical professor of obstetrics in the New York Polyclinic Medical School, attending obstetrician to the City Hospital, Misericordia Hospital, and the New York Polyclinic Hospital, and a member of the New York State and County Medical Societies, and the West Side Clinical Society, died suddenly at his home, from cerebral hemorrhage, on December 13, aged 55 years.

Dr. FRANCIS HENRY BARNES of Boston, a graduate of the Harvard University Medical School, Boston, in 1893, died at his home in Fitchburg, Mass., after a long illness, on December 11, aged 48 years.

Dr. WILLIAM E. SCRIBNER of Detroit, Mich., a graduate of the Michigan College of Medicine, Detroit, in 1883, and a member of the Michigan State Medical Society and the Wayne County Medical Society, died at his home on December 3, aged 56 years.

Dr. ONOFRIO ABRUZZO of Brooklyn, a graduate of the College of Physicians and Surgeons, New York, in 1882, died at his home on December 7, aged 74 years.

Obituary.

JOHN ORLANDO ROE, M.D., LL.D.,

ROCHESTER, N. Y.

Dr. JOHN O. ROE of Rochester, N. Y., one of the leading laryngologists of the country, known especially for his work in plastic surgery of the nose, died on December 24. He was born in Patchogue, Long Island, on February 3, 1849, and was graduated from the College of Physicians and Surgeons, New York City, in 1871. He was a fellow of the American Medical Association and of the American College of Surgeons, a member of the American Cliniatological Association, the American Laryngological Association (of which he was one time president), the American Laryngological, Rhinological, and Otological Association, of the Medical Society of the State of New York (of which he was one time president), and many other medical societies. He was the author of numerous articles on diseases of the larynx, nose, and ear in various periodicals and systems of medicine and surgery.

Correspondence.

ABNORMALITIES IN THE CERVIX UTERI.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I have noticed in the course of my practice two abnormalities in the cervix uteri which, so far as I have been able to find, are not mentioned in any of the textbooks. One was a sort of hypospadias of the cervix. It was in a woman about twenty-three years old, mother of one child. She came to me to be treated for a cervical catarrh. At the tip of the cervix there was a circular aperture, just as in a nullipara, but the canal ran only about a centimeter. The real os externum was about midway up the posterior surface of the portio vaginalis. There was no laceration.

The other case I came across last winter. The subject was a young woman married five weeks. She had complained of a bloody discharge ever since her marriage. On examination I found an untorn circular hymen that did not admit the finger, but that could be pushed upward for some distance in the shape of an inverted funnel. Intercourse, she told me, had taken place a number of times. To reach the cervix I had to tear the hymen, and I found the following condition: there was an intense inflammation of the vagina and cervix, which were bathed in a sanguineous secretion. On swabbing out I found that the external mucous membrane of the cervix was thrown into rugæ, like that of the vagina. These rugæ were longitudinal, converging toward the os externum, while at the cervicovaginal junction there was a circular pleat surrounding the cervix like the collar of a sweater. Has a similar condition ever been reported?

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MORE ABOUT PARATYPHOID—COMMON INTESTINAL PROTOZOA OF MAN.

LONDON, Dec. 10, 1915.

PARATYPHOID has continued to occupy much of the attention of the profession and there was a further discussion about it on the 23rd ult., when Sir William Osler showed the temperature charts of a case of his own, and others from the original article by Professor Achard of Paris, who first differentiated the disease.

Sir William Leishman related his experience in France, where the cases had not exceeded 1200 during the first fifteen and one-half months of war. Nor were they grave as regards life, a point also noted by Sir B. Dawson. Eighteen died, the case mortality being 1.5 per cent. only; there were 32 deaths from combined typhoid and paratyphoid A and B, the latter comprising approximately two-thirds to three-fourths of the infections. Stringent measures to prevent the spread of the disease were taken. At the clearing stations all suspicious cases were subjected to a blood test, and the officer sending the man was informed by telegram that a look-out might be kept for any further case, and if any occurred a bacteriologist carried out a thorough investigation. A spot map was kept at headquarters on which such cases were charted unit by unit. House to house visiting was carried on, infected persons being thus detected. He did not admit that mild cases were not recognized in France.

That opinion was founded on Dreyer's method of agglutination, which he thought needed "controls" before being entirely accepted. There were many cases of mild fever at the front, but it could not be held that they were all of the paratyphoid kind. Trench fever, *e.g.* gave no agglutination; it was a definite disease and he thought perhaps mosquito-borne. He was not satisfied that Castellani's evidence as to the value of mixed vaccines was conclusive; the dosage was too small to give protection and we ought not to tamper with the typhoid element. The incidence of paratyphoid was, roughly, 1 per 1000, so the need for protection against it was not very great, at any rate in France.

Fleet Surgeon Bassett-Smith spoke of naval cases at the Dreadnought Hospital, the Haslar Hospital, and elsewhere. Most of them had come from the Dardanelles. About the middle of the last year a vaccine was prepared from strains obtained in Gallipoli. A blood culture was made in every case of pyrexia. The excreta were examined and agglutination performed if sufficient blood was available. He had come to regard all cases from the near East labeled as dysentery as potential examples of paratyphoid. No patient had died. In the navy they had considered it worth while to provide immunity if possible and had used a vaccine with increasing frequency. The typhoid vaccine had been administered first in two doses, then paratyphoid in one or two. More recently a mixed or triple vaccine in two doses. No more complaint of disturbance was made than after simple antityphoid and the agglutination was satisfactory. He hoped the protection against typhoid was full, against others moderate.

Professor Castellani gave some of his experiences in Ceylon and in Serbia. In the former the most frequent type of the disease was paratyphoid A; in Serbia it was B. In general the disease was milder than true typhoid and did not last so long, but there were many exceptions. He had seen cases lasting three or four months and some proving fatal.

In treatment he adhered to the old plan of liquid diet during the fever and some days after. He had witnessed disastrous results from the modern departure from strict dieting. As to drugs he agreed with Osler: the less given to typhoid patients the better, though hexamethylenamine was useful as a preventive of both gall and urinary bladder complications. Vaccines had not given him such brilliant results as some authorities have reported. He used them in atypical cases of a low type running a protracted course. For prophylaxis mixed vaccines were our chief hope. As the use of mixed vaccine generally was based on his own work, he had answered the objections that some have made, *e.g.* that the amount of each being smaller, that for true typhoid—the most important—would give less protection than the ordinary mono-vaccine for it. But experiment was not in favor of this inference. In fact all experiment hitherto went to show that the mixed vaccine protected against all three diseases—a mono-vaccine against the one. Moreover, the reaction was not more severe. The conclusion suggested was that we should substitute the mixed (typhoid, paratyphoid A. and paratyphoid B.) in enteric prophylaxis for the ordinary mono-typhoid vaccine.

Dr. Hy. Robinson said acute onset was not uncommon. Epistaxis occurred in about 30 per cent.

of the cases. The leading symptoms were headache and abdominal pain, but backache and vomiting were not rare. The spleen was large, as found by percussion, but not often palpable. Spots on the subsidence of the fever, not often earlier, might be larger and more prominent than in typhoid. Abdominal reflex occurred as in typhoid; bradycardia during convalescence generally. The variation of pyrexia was great—it might last five or six days or continue for three or four months. He did not think A. and B. paratyphoid could be differentiated. He thought many mild cases were never diagnosed.

Dr. H. L. Tidy had obtained the bacillus of paratyphoid from 66 cases. In a number he got no agglutination of the *B. typhosus*, although the men had been inoculated within eight months. Pyrexia seemed to remove the agglutinins from the blood—a point for those studying the persistence of the Widal reaction. A positive Widal reaction was equally invaluable in the inoculated and in others. After disappearing the agglutinins occasionally returned; febrile conditions changed them into agglutinoids. For separating the organisms Brown-ing's method was best; for culturing, MacConkey's.

Captain Kenny gave his experience at Taplow with eleven cases probably typhoid, twenty-two diagnosed as paratyphoid B, three as paratyphoid A. He related a case in which at the post-mortem lesions of both typhoid and dysentery were found.

Drs. Carl Browning, Scott Tebb, and Stolkind (of Moscow) also spoke and the discussion was wound up by a few words from the president, Sir W. Osler.

Dr. Wenyon has given a good description of the common intestinal protozoa of man to the Welcome Bureau. He has had the opportunity of studying them at the School of Tropical Medicine here as well as in several other countries. He reports seeing recently a good many instances in persons returned from Gallipoli in whom *Entameba coli* was common as were also the flagellates, trichomonas, tetramitus, and lamblia. *Balantidium* did not come under his notice but it had recently been reported from Egypt. The vegetable organism *Blastocystis* was met with in large numbers. Occasionally a small ameba of the limax type was found. He had seen only four cases of *E. histolytica*—probably because cases were cut short by treatment with emetine which rapidly kills the organism, thereby preventing the formerly frequent sequel—amebic abscess of the liver.

1. Disinfection of Septic Joints. Frederic J. Cotton.
2. The Bacterin Treatment of Certain Chronic Pyogenic Dermatoses. Charles C. Dennis and John H. Bufford.
3. Alopecia Syphilitica. Douglass W. Montgomery.
4. Examination and Prophylaxis for Syphilitic Patients and Their Families: Methods of Examination at the Psychopathic Hospital, Boston. Helen W. Wright.
5. Estimate of the Cost of Social Work in Connection with Examination and Treatment of Other Members of Families of Syphilitic Patients Throughout the State, Based upon 147 Cases Dealt with in Eight Months at the Psychopathic Hospital, Boston.

1. **Disinfection of Septic Joints.**—Frederick J. Cotton declares that to-day the opening and drainage of joints should be listed not as an operation but as a crime. It is our duty to-day either to determine and declare joint infection hopeless, and then to lay the joint wide open (not drain it), or else to bend all our efforts to an optimistic attempt to save the joint; not only to get it healed but to preserve its function as well. He de-

scribes the technique which he has evolved which consists in opening the joint, irrigation for fifteen minutes by the watch with a full stream of 1-15,000 corrosive sublimate, flushing out the excess with salt solution, and then making a water tight closure of the capsule by mattress and single sutures in such a way as to leave the synovial membrane cut edge to cut edge as accurately as may be. The external wound is left wide open or nearly so. The writer cites six cases illustrating different types of infection in which he has used this method successfully and states that it has one very definite limitation and that is that he has not yet worked out any scheme for using it in infection of the closed joints, hip, shoulder, ankle, etc. Where the method is practical the results are nearly always perfect.

2. The Bacterin Treatment of Certain Chronic Pyogenic Dermatoses.—Charles C. Dennis and John H. Buford selected for their experiments with the bacterin treatment 70 cases of chronic pyogenic dermatoses in which previous methods of treatment had failed. This series included 35 cases of acne vulgaris, 21 cases of furunculosis, and 14 cases of folliculitis. The 70 cases were also roughly divided into two groups one of which was to receive only autogenous vaccines and the other stock preparations. In both instances the bacterins employed were made by the writers themselves. Before instituting the treatment with bacterins strict rules were given for the hygienic care of the person, the bodily functions were regulated, and the diet revised and prescribed. The writers describe their method of preparing and administering the vaccines and tabulate their results. Sixty-four per cent. of all cases treated by bacterins were cured, 20 per cent. were benefited, and 16 per cent. received no benefit whatever. Auto-genous vaccines were superior to stock vaccines excepting in the treatment of furunculosis, where no difference could be seen. In most cases a permanent cure resulted from the use of the vaccines. In acne the best results were obtained in the indurated type. The comedo type responded less favorably and the furuncular type least favorably. Of the three pyogenic dermatoses, the best results were obtained in furunculosis. The action of the bacterins in the treatment of sycosis was very erratic. The main object of all bacterin therapy is to raise the resistance of the individual to the specific organism which is responsible for the pyogenic formation, but it cannot correct those faults which underlie the formation of these lesions and for that reason the general treatment described was instituted and to this due credit is given for the part it played in the treatment of acne.

3. Alopecia Syphilitica.—Douglass W. Montgomery expresses the opinion that a knowledge of the peculiarities of this form of alopecia is of value in that it may lead to a search for other luetic symptoms, and so clear up an otherwise puzzling condition. Syphilis sometimes causes a baldness that is so typical as to be almost pathognomonic of the disease. It consists of thinned out, irregular, indefinitely bordered places about the size of the end of a lead pencil or less, making the hair look as though it had been cut by running the point of the scissors up into it. A spotted alopecia resembling this may be produced by pyogenic infection, but in such cases the affected area will be reddened in its entirety or there will be a red spot in the center of the thinned out patch, or even a scar as a symptom of the foregoing pathogenesis. In seborrhea and alopecia areata the bald patches are larger and less numerous than in alopecia syphilitica. The pseudo alopecia areata of Brocq is essentially different from syphilitic alopecia in that the alopecia of Brocq comes on slowly, assumes

its spotted character after long years, is absolutely atrophic, and the patches remain irreparably bald, the surface being cicatricial.

1. Maternity Insurance.—Lee K. Frankel reviews the history of motherhood protection through voluntary philanthropic agencies and through maternity insurance, and discusses legislation affecting motherhood; the philosophy of maternity insurance; present methods of protecting motherhood, particularly along lines of social insurance in European countries; the cost of maternity insurance; developments in the protection of mothers in the United States, and the possibility of organizing a scheme of social insurance under which cash benefits and medical attendance will be given to women during the period of maternity. He states that if it is deemed essential to develop a scheme of insurance under which maternity benefits be paid to working mothers, attention should be called at this time to the desirability of extending these benefits to other women as well. To do this most effectively it would be advisable not to attempt to organize a special maternity insurance, but to incorporate this into a general sickness plan. The need for sickness insurance can no longer be denied. It would be quite simple to incorporate in a plan of sickness insurance the necessary provisions under which all women, whether employed or not, could be made beneficiaries at the time of maternity.

2. Radium in Nervous Disorders.—Alfred Gordon, led by the claims made for soluble radium salts when injected into the circulation, has made experiments on dogs in order to demonstrate what its effects are when brought into direct contact with the central nervous system. The phenomena observed tend to prove a direct effect of radium solution on the fibers of the pyramidal tract and on the erection center in the lumbar segment of the cord. The appearance of a spastic state of the legs following an intradural injection of radium solutions in two animals was so striking that a further experiment was undertaken which gave a similar result. It seemed that no matter how feeble the emanations of radium may be they are not of indifferent character when brought into contact with living tissue. The effect of very feeble emanations of radium have a damaging effect on nervous substance, which appears to be, in animals at least, of a stimulating and irritating character. Caution consequently should be exercised in using soluble radium salts in organic diseases of the nervous system, at least by the intradural method.

5. Mixed Vaccines.—Alphonse A. Thibaudeau states that being acquainted with the results of experiments on laboratory animals which showed that the injection of bacterial derivatives resulted in an increase in the opsonic index of the animals, and that the increase in this index was specific, being raised to those germs only which were used in the preparation, he has endeavored to correlate these two assumptions with the opsonic theory of Wright and the phagocytic theory of Metchnikoff. He selected for his study of the blood

surgical patients who had proved refractory to regular treatment and observed the changes produced by the injection of phylacogen from which he concludes as follows: 1. The intravenous administration of phylacogen is followed by a prompt (about four hours) and marked leucocytosis, which is seen by making leucocyte determinations at two hour intervals. 2. A considerable increase in the proportion of polymorphonuclear leucocytes is also noted by the same means; therefore, the actual number of these leucocytes (phagocytes) is markedly increased. 3. The intravenous administration of mixed vaccines in these cases promptly increased the opsonic index to the infecting microorganisms isolated from the patient, even when they were of two or more species. 4. These phenomena are usually (not always) synchronous with certain characteristic changes (rises) in the pulse, temperature, and blood pressure, which are followed by a fall to normal or even subnormal. 5. Coincidental with the phenomena noted above was marked improvement in the clinical condition for which treatment had been instituted. 6. Mixed vaccines, in their opinion, represent multiple antigens, their therapeutic efficiency being due to their ability to stimulate the formation of antibodies. 7. Their action resembles in a general way that of bacterial vaccines. The action, however, is more prompt (1, 2, and 3 above), owing probably to the elimination of the delay incident to the splitting of the bacterial cell, the metabolic products (bacterial derivatives) concerned in their action being immediately available. At the same time their action is probably not as permanent as that of the vaccines, because of their more rapid absorption.

6. **Retroversion of the Uterus.**—A. N. Clagett makes a preliminary report on an operation which he has devised for suspension of the uterus. He describes in detail the technique by which he shortens the round ligaments and follows this by a modified Gilliam-Ferguson procedure. The result is that the uterus is suspended not only by the strong proximal portion of the round ligament, but a second suspension and normal ante-flexion are obtained from the distal portion. Control examinations have shown the uterus hanging in ante-flexion and freely movable. Occasionally the operation has seemed to be contraindicated by reason of the scanty amount of round ligament muscle present. The writer is unable to state how pregnancy may be affected by this procedure.

7. **Allen Treatment of Diabetes Mellitus.**—Arthur Bookman reports his experience in treating 24 cases of severe diabetes at Mount Sinai Hospital and the Montefiore Home and in private practice during the past year. His results agree with those of Dr. Allen and of others who have used this method. The patients have rapidly become sugar free and with few exceptions have improved in every way. The results in the juvenile cases have been most convincing. The writer believes that in the management of severe diabetes the Allen method is a great step in advance, that it brings excellent results and brings them quickly. He finds this method perfectly feasible under the ordinary condition of private practice. In the way of laboratory examinations only the usual tests for acetone, diacetic acid, and glucose are indispensable.

1. **Kinetic Drive.**—George W. Crile. (See MEDICAL RECORD, page 766, Vol. 88.)

2. **The Treatment of Parotid Tumors by Radium.**—Richard Weil says it is unquestionably a matter of importance to determine whether or not a particular type of tumor is especially suitable for radium treatment. Not all of the cases so treated have been cured, and it would make for a greater precision in treatment if it were possible to determine that certain types of parotid tumors respond to treatment whereas others do not. In the case reported a portion of the tumor was removed for diagnosis and found to belong to a type that has caused considerable discussion, that to which Billroth gave the name cylindroma. The independent position of these tumors among adenocarcinomas gives a rational ground to expect that they will react to therapeutic measures in a somewhat exceptional manner. In the instance under discussion the tumor was of seven years' duration. It was treated for a period of six weeks by the insertion of radium into the tumor. This was followed by the disappearance of the tumor which after two years shows no recurrence.

3. **Trichinosis.**—Leon Bloch reports a case in which trichina larvæ was found in the spinal fluid. From the observation of this case he concludes that meningeal irritation undoubtedly existed as was shown by the positive Nonne and Noguchi tests; that severe infections show a low eosinophile count during the acute stage, which increases with convalescence, and that vigorous catharsis with a view of clearing the intestinal tract of all parasites which have not yet penetrated the mucosa appears to have limited the infection. The writer points out three ways by which the parasites may enter the spinal fluid, namely, directly through the central capillaries of the choroidal villi, through the perivascular lymphatics, and directly through the cerebral cortex into the subarachnoid space.

4. **Trypanosomiasis.**—J. Frank Shamburg, John A. Kolmer, and George W. Raiziss give the results of their experiments on a series of rats infected by intraperitoneal injection with *Trypanosoma equiperdum* and then treated with various therapeutic agents. The only drugs which they found capable of destroying the *Trypanosoma equiperdum*, and indeed trypanosomes generally, in the blood of infected animals were salvarsan and neosalvarsan. They tabulate the results of intravenous injections of salvarsan and neosalvarsan, both the German product and that of the Dermatological Research Laboratory, in experimental trypanomiasis which show that the two preparations do not vary materially in their trypanocidal influence. Both products in adequate dosage are capable of producing a permanent sterilizing effect. In commenting on the clinical results obtained with their product, the writers state that they have administered their arsenobenzol intravenously over 175 times without any accident whatsoever. In a proportion of the cases there have been some reactive symptoms which passed away in the course of a few hours. The therapeutic results they

believe to be indistinguishable from those obtained with the German product. A healing influence on lesions is often evident in from twenty-four to forty-eight hours. Several hundred doses of this product have been administered by others than themselves and the reports from these correspond with the observations of the authors.

5. **Beriberi.**—Allen M. Walcott says that beriberi is, as yet, a very common disease in the Brazilian portion of the Amazon basin. There has been an impression that perhaps the disease in Brazil is different from that found elsewhere, but such is not the case. The disease is the same in this locality as elsewhere. Experiments with farina de agua (a product of prolonged maceration of wild or poisonous manioc, more esteemed among the Brazilians than bread and partaken of in quantity, especially by the laboring classes at all meals) have been carried on by the writer with chickens. It has been found that it produces in fowls a condition clinically the same as avian polyneuritis or beriberi. These experiments indicate a very important source of beriberi not usually met in other parts of the world. Its cause, however, is the same as that found elsewhere, a lack of vitamins in the food. The eradication and cure of the disease in this locality consists in changing the diet so that it will furnish a sufficient amount of vitamins.

6. **Paresis.**—Graeme M. Hammond and Norman Sharpe describe their experiments with the intraventricular injection of salvarsanized serum in paresis and believe that this method possesses certain advantages over the subdural and intraspinal routes, in that placing the serum in the lateral ventricles is placing it subarachnoidally at once, this insures an even distribution over both hemispheres in juxtaposition to the cortical cells before it is drained out of the cranium and obviates the lumbar puncture which is necessary in the subdural method before the serum is introduced. It brings the serum in contact with tissues that are not reached by the subdural route, namely, the ventricular system and the base of the brain, and finally it may reach the perivascular sheath spaces which extend between the neurons deeply into the brain substance and drain it of waste products, communicated directly with the subarachnoid space. In comparison with the deadly nature of paresis, the hazard of intraspinal treatment, by whatever method, is of little moment. The intraventricular method, with careful technique and a due regard for the anatomy of the brain and the delicate nature of the tissues one is invading is practically free from danger. If the freedom from unfavorable symptoms so far achieved in the intraventricular injection can be maintained, it will be imperative to so treat paresis in its earliest stages, with greater chance of marked improvement and perhaps permanent arrest of symptoms.

7. **Hemiplegia.**—Shepherd Ivory Franz, Mildred E. Sheetz, and Anita A. Wilson state that a few casual observations made some years ago, animal experiments by one of the writers, and the experimental results obtained by others, suggest the possibility that conclusions regarding the permanency of paralysis from cerebral accidents have been neither accurate nor scientifically grounded and that more attention should be paid to the possible improvement of these cases. The results in the five cases reported show clearly the possibility of a return of function in a paralyzed segment even after the paralysis has existed much beyond the time limit set by some neurologists for possible improvement. Furthermore, there appears at present no indication of a limitation of the quantity of the improvement which may be attained by suitable and sufficiently prolonged

therapeutic measures. Improvement has taken place almost equally well whether the lesion was cortical or capsular. Properly used massage, passive movements, hot baths and packs, followed or accompanied by attempts to obtain on the part of the patient voluntary muscular contractions should be employed in all such cases. For the recovery of functions such as are under consideration, there are many explanations, the simplest of which is that these are not motor inabilities but exaggerated asthenias. The results of experimental lesions in animals agree with the observations on man. Such differences as exist seem to be of degree or completeness of functional loss and of time of motor recovery. In animals the residual symptoms are more commonly those of asthenia, or of ataxia, or of paratonicity, rather than complete motor inabilities and contractures.

10. **Lesion Differentiation.**—J. Gordon Wilson and F. H. Pike consider three symptoms common to lesions in the labyrinth and in the cerebellum, namely nystagmus, vertigo, and ataxia, confining themselves to lesions which are strictly and definitely labyrinthine and those which are strictly and definitely cerebellar. They find that labyrinthine lesions differ from cerebellar (1) in the existence of Romberg's sign in labyrinthine lesions; (2) variations in the attitude of the head influence, the lack of equilibrium of the body in labyrinthine and not in cerebellar lesions; (3) an affection of the labyrinth does not definitely involve those movements of isolated parts which result in dysmetria; (4) in labyrinthine disease movements of rotation or disorientation are not so readily perceived. In mixed cases the diagnosis is more difficult. If, however, one can exclude with these data the purely local labyrinthine and the purely local cerebellar lesions he can proceed intelligently to cases that involve both structures.

1. **Gunshot Wounds of the Lungs.**—W. Hale White says the most striking thing in connection with gunshot wounds of the chest is that their effects are not more serious. Some patients are killed at once or die soon after; others have grave results as empyea, still in dealing with large numbers he was greatly impressed with the extreme good fortune of many who were hit in the chest. Some bullets seemed almost to thread their way between important structures in the thorax and so evade them. One man had his left recurrent laryngeal nerve damaged by a bullet and yet the large vessels were unhurt. Usually there is some pain when the bullet enters the chest, but exceptionally the patient may be hardly aware that he is hit, and then he suffers neither from pain, hemoptosis, nor dyspnea. Perhaps the last is the commonest symptom. Both in intensity and duration it is most variable. Hemoptosis is very common, occurring in at least three-fourths of the cases, probably more. Doubtless it is at times immediately fatal, but if it does not kill soon, it rarely, if ever, does later. Hemothorax is frequently seen,

the physical signs being those of fluid in the chest. From the physical signs it is impossible to tell these cases from ordinary pleuritic effusion, except from the history of the wound. Pyrexia is quite common with hemothorax and does not always mean microbic infection. These patients frequently get well without removing any of the fluid from the chest by aspiration or laying it open. Microbic infection should be suspected when the evening temperature is high, the daily excursion wide, and the general symptoms more severe than in ordinary sterile cases of hemothorax. The removal of some of the fluid in the chest may accelerate the absorption of the rest, but it is usually wise to take away as much as possible. After aspiration of blood there is no reaccumulation of fluid. Although the physical signs change after aspiration as they do when clear fluid is aspirated, they do not alter as rapidly. The author is impressed with how well the cases of hemothorax do when left alone. It is probably wrong to withdraw the fluid shortly after injury; on the other hand, it may be well not to delay too long for a lung that is compressed for some time takes a long time to re-expand. In very few of the patients with bullet wounds of the chest had the bullet struck the rib and run around it. There were in this series of cases no serious external hemorrhages. The outlook for these patients is good as a number of illustrative cases shows. In cases in which there was a bullet embedded in the lung it has been left alone and in no instance has its presence done any harm.

2. **Urea as Bactericide in Wounds.**—W. St. C. Symmers relates his laboratory experience with urea as a bactericide. He concludes that in urea we have a substance which in the dry state is permanently stable, practically non-poisonous, highly diffusible, and which even in low concentration (3 per cent.) affects the growth of bacteria, is inhibitive to growth at 8 to 10 per cent., and which is markedly bactericidal to non-spore-forming bacteria in the higher percentages. This bactericidal effect is active in the presence of blood and like organic fluids. Moreover urea is non-irritating to living tissues; the dry substance may be sprinkled over wounds to almost any extent without any injury to the parts.

J. N. Kirk adds a clinical note to the above stating that during the past four years they have been using urea clinically and fluid that it is innocuous to animal tissues; that in quantities that can be used in wounds it is nontoxic; that by its use at least half the labor necessitated by other methods of treatment is saved; that during its use the processes of repair are not retarded. The most striking results will be obtained by its use as a first aid dressing since it prevents suppuration arising in wounds from chronic blood infections.

3. **Perforation of Gastric and Duodenal Ulcers.**—Richard Warren bases this paper on 40 cases which have come under his care during the past six years. Of these 40 cases, 29 were men and 11 women; all were subjected to operation, with a mortality of 35 per cent. A notable feature was the excessive mortality of gastric as compared with duodenal ulcers. The mortality of the gastric ulcers was 54 per cent. and that of the duodenal and pyloric ulcers 25 per cent. The mortality bears a pretty definite relation to the time that elapsed between perforation and operation. After twelve hours the prognosis becomes grave, yet cases have survived in which perforation has apparently been present for two days or more. The author tabulates the various operations used and their results in gastric and duodenal ulcers and calls attention to the uses of jejunostomy where the patient's

condition is extremely grave and every moment spent on operation is of importance. He advises in such instances simply occluding the ulcer with one or two sutures, placing a gauze drain around the site of perforation, and performing a jejunostomy for the purpose of feeding the patient early.

7. **Spontaneous Rupture of the Uterus with Unruptured Membranes and Accidental Hemorrhage.**—E. Macibone reports this case and Lewis Graham comments upon it. The patient was admitted to the hospital in a grave general condition during labor. The diagnosis was obscure, and as the patient appeared too ill to stand a natural labor, an exploratory operation was decided upon with a view to cesarean section. The uterus was opened longitudinally in front in the midline. The placenta was found at the fundus but completely detached from the uterine wall and separated from it by a large mass of blood clot. The placenta and membranes and their contents were removed without rupturing them. The foetus was dead. The uterus was found to have two transverse lacerations on the posterior wall. There were also about a half a dozen other lacerations but not so long or deep. Subtotal hysterectomy with peritonealization of all the stumps was done. The patient made an uninterrupted recovery.

8. **Prolapse of the Lung through a Deficiency in the Anterior Portion of the Diaphragm.**—J. N. Kilner reports this case which is of interest because the symptoms were all referred to the abdomen. A swelling occasionally appeared above and to the right of the umbilicus. Cough or other effort by no means resulted in the appearance of the swelling, which was first seen when the patient was lying still in bed. The movements of the tumor might easily have been mistaken for peristalsis; they were, however, too quick and irregular in volume and occurrence. The support given by dressings and bandages and later the formation of adhesions between the liver and the abdominal wall may have prevented the descent of the lung after the laparotomy. Six months after discharge from the hospital the patient reported a return of the pain but no reappearance of the swelling up to date.

1. **Gas Poisoning.**—Leonard Hill calls attention to the different varieties of poison gases. There are some which kill by cutting off the supply of oxygen, others which paralyze the respiratory center, and another set which acutely irritate the respiratory passages, causing exudation of lymph which drowns the subject. This last set of gases, particularly chlorine and bromine, the Germans have made use of for two reasons. First, because they put a man out of action when breathed for a shorter time and in greater dilution than any other poison gas, and, secondly, because they are heavier than air and so suitable for drifting with the wind. The effect of 1 in 10,000 chlorine is

such that no man could endure breathing it who could escape from its influence. The eyes and the mucous membranes of the respiratory tract are intensely irritated and a watery exudation takes place, the inevitable effort of the living tissues to dilute so irritant a poison. The chlorine poisoning of the lungs is comparable to extensive burns of the skin, and the same general treatment to support strength and lessen shock is required. For the severe cases the one object must be the getting rid of the exudation in the air tubes which is drowning the victim. For this purpose rhythmical compression of the thorax and artificial respiration give temporary help. Emetics have proved useful in less critical cases. The administration of oxygen relieves the cyanosis and improves the condition of the subject. Just as septic infection of the skin is the sequel of a burn, so pneumonia and bronchitis follow chlorine poisoning. In experimental animals severe poisoning has in every case had this end, and thus far no means of preventing it has been found. The most notable symptoms of a typical case of gas poisoning are cold with a subnormal temperature, restlessness, slow pulse (except in collapsed cases), intense cyanosis, jerky respirations, often numbering 40 a minute and accompanied by coughing, choking, and frothy expectoration. The writer also describes the pathological conditions found post mortem and his experimental work on animals.

2. Gunshot Wounds of the Abdomen.—A. W. Mayo-Robson relates his experience while serving in the Dardanelles on various hospital ships where the cases were brought in from two to four hours after being wounded. In a former experience in a base military hospital in London he had been impressed by the absence of abdominal cases in their wards; the explanation is clear, the cases seldom reached the base hospital as wholesale the expectant treatment was a failure. Some little experience of the course of cases treated by opium, starvation, and rest soon convinced him that a clean bullet wound through the abdomen, with small wounds of entry and exit, and without evidence of internal hemorrhage or extravation, might, if favorably situated, be treated expectantly; whereas a bullet wound with large openings of entry and exit, or with signs of internal hemorrhage, and with absence of liver dullness should be operated on as soon as possible if seen early and if the general condition of the patient is favorable. As nearly all shrapnel, shell, and bomb wounds are septic and produce great visceral injury, operation will give a better chance of success than expectant treatment if the patient is in condition to bear it. If the case is seen late and peritonitis has already set in, a small incision above the pubes, large enough for the insertion of a drainage tube down to the bottom of the pelvis, and the Fowler position, will give the patient a chance of recovery. (This treatment is also best for typhoid perforation.) A number of cases are cited for the purpose of giving some idea of the conditions for which operation may be required.

3. Field-Ambulance Work at Anzac.—C. Makie Begg writes a note on the special difficulties and dangers which beset field ambulance work. At first they did no operations except for the arrest of hemorrhage. However, on making inquiries at the hospital ships they learned that the results of abdominal wounds were extremely bad. They then erected an operating tent on the beach and tried operating on shore on almost all cases of penetrating abdominal wounds, and kept the patients on shore for twenty-four hours to four days afterward. They found in about 60 per cent. of the cases operated on the condition was hopeless, whether the wound was caused by bullet, shrapnel, or shell

fragment. As a rule the gut was torn or perforated in from seven to twenty places and several of the mesenteric arteries were usually torn across. Most of these cases died in a short time, but a few of them were sent off to the ships in surprisingly good condition. About 25 per cent. of the cases gave good hopes of a favorable result. They operated on a considerable number of head injuries, principally depressed fractures and ruptured meningeal arteries. Of the latter they saw a goodly number, some of which were of special interest. From their experience the writer concludes that early operation, by which is meant any time up to six hours, is desirable in abdominal injuries and also rest at the place of operation for three or four days afterwards. With the Turkish bullets, shrapnel and shell wounds the results are extremely bad.

4. A Supposed Soluble Toxin.—G. Narger and H. H. Dale give an outline of certain experiments on the nature of a toxic substance occurring in the filtrates from cultures of the bacillus of malignant edema. They finally found, however, that there is no ground for supposing that the bacillus of malignant edema, in an artificial culture of the type described, produces anything in the nature of a specific toxin. The production by it of a toxic solution from meat depends on its intense proteoclastic and disseminating action. The proteins are rapidly broken down to amino acids, and from these the amino groupings are then split off, yielding ammonium salts of fatty acids, which accumulate in surprising concentration. To these must be attributed at least the greater part of the acute symptoms produced by the culture filtrate in the guinea pig. The chief interest in the observation seems to be the hint that it furnishes as to one of the factors favoring spread of infection with the bacillus in the tissues of an animal. Given injured tissues in which the growth may start, it is evident that the localized production of ammonium salts will soon be sufficient to create in the neighboring tissues conditions favoring the spread of the growth. Their conclusions seem to the writers to make clear the futility of attempting to obtain an antitoxin to the products of the bacillus of malignant edema.

12. Spinal Injuries of Warfare.—Gordon Holmes has during the past thirteen months made observations on 300 cases of spinal injury which form the basis of his remarks and conclusions for two lectures. He describes the clinical symptoms of this class of injuries and correlates them with the localization of the lesion. He states that the segmental level of the lesion can usually be recognized as accurately by the extent of the motor paralysis as by the upper border of the sensory disturbance. When one of the lower abdominal segments is involved the level of the lesion may be accurately determined by observing the segment below which the abdominal cutaneous reflexes cannot be obtained. He discusses reflexes, reflex tones, spinal shock, automatic movements, servical softening, palsy of the cervical sympathetic, in connection with which he calls special attention to an interesting type of cases that have been observed as a result of injury of the lower part of the cervical enlargement. These were characterized by subnormal temperature, even 80° Fahr. and below, slow pulse, low blood pressure, and scanty secretion of urine. All of the ten patients in whom these symptoms appeared died within ten days after the infliction of the wound. Polyuria was observed when the injury was in the middle of the dorsal cord, probably due to paralysis of the sympathetic fibers. The writer also calls attention to various trophic disturbances, joint changes and herpes in connection with this class of injuries.

Industrial Poisoning from Celluloid Varnish in the Aeroplane Industry.—Koelsch refers to the use of this varnish upon certain portions of the machines to secure the maximum of smoothness and nonresistance to air, and also to protect against the influence of weather conditions. As a rule four coats are applied with a hand brush. The varnish represents solutions of non-combustible acetyl cellulose, and it is very difficult to hit upon proper solvents. Many substances have been tested for this purpose, and the best appear to belong to the aliphatic series (chloroform, carbon tetrachloride, etc.), next in order coming acetone, acetate of amyl, formic acid, etc. Numerous commercial preparations have been placed on the market. In order to keep the formulae secret the manufacturers seem to alter them from time to time. The varnishes are by no means harmless to those who handle them. The acetylene-tetrachloride varnish, which is very largely used, appears to be injurious both from contact and by inhalation. The changes induced are general, and consist of profound metabolic disturbances. Fourteen cases of poisoning, two fatal, have been recorded. Two types are represented, one characterized by gastroenteric symptoms (nausea, vomiting, pain), and especially enlargement of the liver, with jaundice. Anemia and visceral hemorrhages were noted in certain cases. In the other type nervous phenomena predominate, as headache, paresthesiae, tremor, pareses, etc. Other solvents have also produced characteristic symptoms in isolated cases. The author relates nine cases in workmen of acetylene tetrachloride poisoning. As a rule wrong diagnoses were made at first—either lead poisoning or jaundice. The sole remedy is, of course, to forbid the use of this substance in making varnishes. Other things besides lead can cause colic in a painter, and we must no longer regard the association "painter-colic" as absolute. Even the fact that some of these victims had used no lead colors for months, the author says, was not at first rightly interpreted.

An Antitoxin for Malignant Edema.—Kathariner does not refer here to the malignant form of anthrax, but to the condition known as fulminating gangrene, progressive gangrenous emphysema, gangrenous gas phlegmon, etc. This form of wound infection agrees in some respects with ordinary gas gangrene, doubtless because of the similarity of the exciting agents, but in the main the clinical courses differ considerably. As far back as 1881 Koch described his bacillus edematis maligni, three years after Pasteur had discovered his septic vibris. Quite recently Roux has been seeking to obtain an antitoxin from the latter. After several passages of the germ on special media it was found to generate an abundance of gas. The toxin obtained was found extremely virulent. Vibriones were obtained from various localities—the cadavers of infected rabbits, the blood of patients with septicemia, and from the blood of a putrefying cow. All were equivalent in virulence. A horse was immunized carefully and without injury to itself. The antitoxin obtained worked well in laboratory experiments, and was both antitoxic and antiinfectious. This description was published originally in *Compt. rend. d. l. Acad. de Sci. of Paris*, several weeks before the abstract of Kathariner. The latter makes no comment whatever, nor does he allude to any work on the same subject in Germany, or to any account of tests in human subjects. Some weeks ago the lay press announced the discovery in France of a serum against gas gangrene, but as already stated, Kathariner says, the latter is quite another thing from malignant edema.

Exanthem and Recurrence in Epidemic Meningitis.—Morgenstern relates the case of a patient first admitted as a typhus suspect. To complicate matters she had recently gone through an acute disease, which resembled both influenza and rheumatism. The leading symptoms had been severe cephalalgia and arthralgias with a purpuric exanthem. Only ten days elapsed before a fresh sickness appeared which suggested the possibility of a relapse. She broke out anew with an exanthem and again complained of headache. Fever rose to 40° C., and she was slightly confused and restless. The conjunctivæ were injected. Reflexes normal. No Babinski or Kernigeign. All food at once vomited. Constipation. Spleen swollen. The trunk and limbs were covered with a multiform eruption. Along with petechiae was seen a roseolous rash, consisting of both macules and papules. The petechial spots varied in size from a lentil to a penny. There was a second crop of both petechiae and roseola, and as the former grew old a slight necrotic center was sometimes noted. Diazo negative, blood sterile in attempted cultures of Eberth's bacillus. The peculiarities of the exanthem appeared to exclude typhus. The meningeal irritation originally present began to increase in severity. Lumbar puncture brought away the meningococcus of Weichselbaum. Blood cultures were again negative. The punctates later became purulent, although a specific antiserum had been injected. One intravenous injection of collargol was followed by great improvement. Patient made a good recovery and resumed her occupation. Five weeks later she again became acutely ill, and broke out exactly as in the prior attack. The general reaction was much milder. There was no meningism, and she seemed almost well again when the temperature rose with accompaniment of the meningeal syndrome and another crop of the eruption. The lumbar punctate again contained the meningococcus. Nevertheless, the patient again promptly recovered. Epidemic cerebrospinal meningitis is an affection in which true relapses are said to be absent. If this be the truth then the author might regard her case as one of remittent course of the disease, such as has often been noted.

A Recent Smallpox Epidemic in Germany.—According to Hesse smallpox has become so rare in the country about Detmold that many physicians have never seen a case. When it was introduced into this neighborhood by some Polish laborers there was no fresh virus available for vaccination, but "takings" occurred in some cases. Some patients had a mild, nonfebrile disease, diagnosed as varicella. Failure of vaccination to take in these cases is good evidence for variola. In the main building of the county hospital five typical cases developed at once, with four deaths. Two deaconesses in attendance contracted the disease, with one death, and three old men and a young, unvaccinated baby also succumbed. By this time a body of experts had reached the place, quarantine was established (but not strictly carried out), and after a general vaccination with fresh lymph, a considerable number were allowed to go home. Of twelve alleged cases of the disease nine were genuine and three doubtful. Of the former six died. Of the thirty-eight Polish immigrants but three developed the disease, and only one in its typical form. The severely ill patient, a Polish girl, died in an isolation building in the hospital. The only way of explaining the spread of the disease to the main building is by the presence of the hospital cat, which went from place to place, and had been in contact both with the Polish girl and with several of those who later developed the disease.

Book Reviews.

MARIE TARNOWSKA. By A. VIVANTI CHARTERS. With an introductory letter by Professor L. M. BOSSI, of the University of Genoa. Price \$1.50. New York: The Century Co., 1915.

THIS book is practically the autobiography of the murderer, Marie Tarnowska, who is at present confined in the penitentiary of Trani. Professor Bossi takes the stand that her moral obliquity was due to some gynecological condition. The author was moved by this opinion to take a compassionate view of Marie Tarnowska's crimes, and after visiting her compiled the "autobiography." Her own story shows her to have been an egotistical, wilful, and hysterical girl. Her mother had epileptic seizures and two of her aunts are now confined in an insane asylum in Russia. She inherited a weak, nervous system and nothing was done through education to prevent her from succumbing to her abnormal desires for what she knew to be wrong. The author, however, aims to show that her criminal impulse was related to a morbid physical condition, and overlooks the real lesson that is to be derived from her case, namely, that proper training and education might have prevented her downfall.

E. V. BEHRING'S GESAMMELTE ABHANDLUNGEN. Neue Folge, 1915. Price, 10 marks. Bonn: A. Marcus and E. Webers Verlag, 1915.

THIS convenient collection of reprints covering the work on tetanus, diphtheria, and tuberculosis, which have appeared from the laboratory of von Behring in the past two years, offers an excellent review of the progress which is gradually being made along these lines. Time and a very much larger experience only will decide the practical value of the laboratory and clinical experiments herein reported.

THE DEVELOPMENT OF THE HUMAN BODY. A Manual of Human Embryology. By J. PLAYFAIR McMURRICH, A.M., Ph.D., LL.D., Professor of Anatomy at the University of Toronto, formerly Professor of Anatomy in the University of Michigan. Fifth Edition, Revised and Enlarged. With two hundred and eighty-seven illustrations, several of which are printed in colors. Price, \$2.50 net. Philadelphia: P. Blakiston's Son & Co., 1915.

THE study of anatomy nowadays necessitates an enormous amount of work on the part of the medical student. To assimilate the facts which come under the head of descriptive in the time given to the curriculum of medicine, or to assimilate even the more essential facts is a task of great magnitude and one to which often the student is unequal. Consequently, instead of assimilation cramming is too frequently the practice with students and when they have gained their degrees their knowledge is not exact, but somewhat vague. If, however, the student step by step followed the development of the structure and relations of the organs, and thus laid a sound foundation for his subsequent work in this direction, he would be able to do this intelligently and really understand anatomy. This book was written with the idea of presenting a concise and lucid statement of the development of the human body. Dr. McMurrich has succeeded in this endeavor, and his manual of human embryology is a book which has been and will continue to be of the utmost service to medical students. The present edition has been thoroughly brought up to date.

APPLIED IMMUNOLOGY. The Practical Application of Sera and Bacterins Prophylactically, Diagnostically, and Therapeutically. With an appendix on serum treatment of hemorrhage, organotherapy, and chemotherapy. By B. A. THOMAS, A.M., M.D., professor of genitourinary surgery in the Polyclinic Hospital and College for Graduates in Medicine; instructor of surgery in the University of Pennsylvania; associate in the William Pepper Laboratory of Clinical Medicine; and R. H. IVY, M.D., D.D.S., assistant instructor in surgery in the University of Pennsylvania; instructor in genitourinary surgery in the Polyclinic Hospital and College for Graduates in Medicine, Philadelphia. Five colored insets and 68 illustrations in text. Price, \$4.00. Philadelphia and London: J. B. Lippincott Company, 1915.

THE wide adoption of laboratory diagnostic methods in clinical medicine and the employment of bacterial vaccines, salvarsanized sera, and other therapeutic agents based upon laboratory investigations, have necessitated a good deal of education of the practitioner in

the therapeutic limits and dangers of these forms of treatment. A good many deaths have occurred from the careless use of salvarsan and vaccines; and too much information on the subject can not be injected into the minds of practitioners and of hospital internes who so frequently use these powerful remedies with but little knowledge of their nature and effects. For this and other reasons this very practical volume will prove to be of considerable value in furnishing information on many phases of the general subject of immunology, on the methods of carrying out many of the more complicated laboratory tests, and on the preparation of vaccines and sera. It is well illustrated with useful diagrams, and is modern in the discussion of the various tests and methods.

THE STARVATION TREATMENT OF DIABETES. With a Series of Graduated Diets as used at the Massachusetts General Hospital. By LEWIS WEBB HILL, M.D., and Rena S. Eckman. With an Introduction by RICHARD C. CABOT, M.D. Price, \$1.00. Boston: W. D. Leonard, 1915.

THE starvation treatment of diabetes mellitus has now been employed for some time, long enough, in fact, to test its value. In this country it was initiated and carried out by Dr. Frederick M. Allen at Harvard, and at the Rockefeller Institute Hospital with a good deal of success. More recently the staff of the General Hospital of Massachusetts at Boston have been carrying out the method and the book under notice gives details of the treatment, diet lists, and so on. The work is highly instructive and may be recommended to those practitioners who desire to try a treatment which has been attended with satisfactory results.

ORTHOPEDIC SURGERY. By EDWARD H. BRADFORD, M.D., Consulting Surgeon to the Children's Hospital, Boston, and to the Boston City Hospital; Professor of Orthopedic Surgery Emeritus in Harvard University, and ROBERT W. LOVETT, M.D., Professor of Orthopedic Surgery in Harvard University; Surgeon to the Children's Hospital, Boston; Surgeon-in-chief to the Massachusetts Hospital School, Canton. Fifth Edition. Octavo of 416 pages, with 369 illustrations. Price, muslin, \$3.75, net. New York: William Wood & Company, 1915.

FOR twenty-five years Bradford and Lovett's Orthopedic Surgery has been recognized as one of the leading authorities in this branch of surgery. Furthermore, it covers the subject as briefly as is consistent with a thorough presentation of all the important points in the etiology, pathology, diagnosis and treatment of the various lesions coming under the special province of the orthopedic surgeon. To accomplish this end, extensive references to the literature have not been indulged in, nor have the authors incorporated extended discussion of the views of other writers, especially upon controversial subjects. This plan was pursued "not in a spirit of ignorance or disparagement of the work of others, but simply in the need of condensed statement" and the reader, in our opinion, is the gainer; for he gets a clear and concise presentation of facts based upon the author's extensive experience in this line of work, and is not confused in the attempt to pick the wheat from the chaff, as would often be the case were a variety of theories and methods of treatment put before him. Without doubt the authors are better able to judge of the merits of a multiplicity of theories and methods of treatment than is the average reader; and while the result of this method of handling the subject is that the authors seem at times to be severely dogmatic, it is certain that one who follows out the plans of treatment outlined in this book will seldom go far astray and will generally be employing that form of treatment which is approved by the majority of orthopedic surgeons. Those who wish to pursue the study of any individual subject further will usually be in a position to consult orthopedic works of the unabridged type.

In addition to an extensive consideration of tuberculous processes in the bones and joints, there are chapters covering infectious osteomyelitis, synovitis, and arthritis; arthritis deformans; the deformities of rickets; coxa vara and coxa valga; torticollis; infantile, spastic and other paralyzes; congenital dislocations; flat foot; metatarsalgia and other deformities of the foot; and a number of other subjects which may properly be classed as belonging to the domain of orthopedic surgery.

There is no doubt that the present revised edition of this work will hold its place as one of the best condensed treatises on orthopedic surgery extant.

Society Reports.

THE PRACTITIONER'S SOCIETY OF NEW YORK.

*The Two Hundred and Seventy-Third Meeting Held,
Friday, Nov. 4, 1915.*

DR. JOHN S. THACHER, PRESIDENT, IN THE CHAIR.

Case of Paget's Disease.—Dr. JAMES ALEXANDER MILLER presented this patient, a man of sixty-three years, who was admitted to Bellevue on July 3, 1915. For twenty years he had been very markedly alcoholic and gave a history of both syphilis and gonorrhea. For the past nine years he had complained of pain in his back, more marked in the lumbar region. He had also in the past two years noticed that his head was growing a little larger and that his height was somewhat less. These were his chief complaints until a few weeks previous, when swelling of the right shoulder was noted with some pain. Physical examination on admission showed the conditions noted in the photographs displayed. The head was large; the clavicle prominent and thickened in the right shoulder, also swollen and somewhat tender with distinct limitation of motion. The bones of the lower extremities were thickened, especially the tibiae which were bowed forward. The patient was up and about the ward and felt comfortable. Since admission there had been increased swelling in the shoulder with marked pain, more in the past month. There was very marked edema of the whole right arm and distention of the superficial veins of the shoulder and upper right chest. About three weeks ago a firm swelling was noted in the anterior surface of the tibia in the middle third. A small section from this tumor, which was firmer than the shoulder swelling, showed spindle-cell sarcoma. Within the past few weeks a small cystic swelling appeared over the left clavicle in the junction of its middle and outer third and also in the right occipital region. These swellings were not tender. The Wassermann test was positive. The urine was normal and negative for Bence-Jones albumin. Physical examination was otherwise negative excepting for cardiac hypertrophy with evidence of mitral regurgitation and considerable pulmonary emphysema with chronic fibrous tuberculosis at both apices. X-ray examination showed an involvement of practically all of the bones of the body. The cranium was very markedly diseased and the right humerus was almost entirely destroyed. A rarifying osteitis was shown in all of the bones of both arms, in most of the ribs, in the pelvic bones, in the vertebrae and in the tibia. The femur showed marked thickening of the bones without rarification. Apparently the only bones not involved were the fibula and the small bones of the hands, feet, and face. The x-ray of the left clavicle showed that the bone was almost entirely gone under the site of the swelling noted. Comparison of the x-ray taken recently with those taken soon after admission showed a very marked increase in the extent and severity of the lesions.

Dr. ABBE asked if the inner table were involved, if the hearing was affected, and if the foramina were blocked. He said it was the most extreme development of the sarcomatous element that he had ever seen.

Dr. DANA asked if there were any signs of tabes.

Dr. GILMAN THOMPSON asked if one plate showed fibrosis of the lungs, and when the symptoms first appeared. He referred to the case of a patient in Bellevue Hospital with osteitis deformans whose condition he had reported in the *MEDICAL RECORD* of May 10, 1913. This woman, although greatly deformed, was in good general health and there was no sarcoma. A similar case was recently studied in Bellevue by Dr. Nammack. Dr. Miller's case was remarkable because of the universal involvement of all the major bones with sarcoma.

Dr. MILLER, in answer to Dr. Abbe, said that the inner table was apparently not involved. There was no interference with the special senses. In reply to Dr. Thompson he said that there was fibrosis of the lungs. There was emphysema, enlarged heart, and probably an old tuberculosis. He added that in the literature seven or eight cases had had sarcomata; five had had carcinomata.

Morbid Somnolence and Its Relations to the Endocrine Glands.—Dr. CHARLES A. DANA read this paper. (See page 1).

Dr. L. A. CONNER said he would like to ask Dr. Dana a little more about the endocrine blood changes,

whether these changes were really characteristic enough to be of any real service in making a diagnosis. So many minor variations were seen in normal people under all sorts of conditions, and a number of things Dr. Dana had mentioned seemed to be so slight as to be of doubtful value. A blood pressure of 100 to 110 in normal individuals was not uncommon. Temperature was frequently slightly subnormal. Thus one often had the greatest difficulty in these confusing symptoms in finding sufficiently marked ones to justify a diagnosis.

Dr. WALTER B. JAMES said his attention was caught by Dr. Dana's term "minor blood changes of the endocrine type." He was going to ask what the changes were. He thought the changes referred to were far from uncommon. In his own laboratory he expected to find this blood picture in many young individuals who were "run down" or "below par" and he expected to find lymphocytosis in this condition. He had not associated this condition with the endocrinal glands.

Dr. ROBINSON said that Pickwick's fat boy must have belonged to this type.

Dr. LONGCOPE expressed surprise at the statement that one patient had taken 700 grams of glucose. How had this been accomplished? Was it by mouth? In his experience it was most difficult to get 200 grams into some patients.

Dr. ABBE said that if there were glandular growth, how was it possible that some cases improved after a while? He knew of one case, of a lady who fell into short sleeps of half a minute. She would drop asleep in the middle of talking, though she had apparently perfect health. During the last year or two she had not done this. If this improvement occurred, it could not have been enlargement of the pituitary. This woman was fifty-five years of age.

Dr. BRANNAN asked was it a case of petit mal?

Dr. NILES said that the Bellevue Hospital case detailed by Dr. Dana had very curious mental symptoms. The boy would follow the physicians around the wards, and when they stopped at a bedside would go to sleep while standing up. He was given 200 grams of dextrose without glycosuria. His blood serum and spinal fluid gave positive Wassermann reactions, and there was an excess of lymphocytes in the latter. Dr. Niles had studied four cases of posterior lobe insufficiency, and in all of them there was a very distinct slowing of the mental processes with hypersomnia. The picture was that of Pickwick's fat boy, as Dr. Robinson had suggested. One boy of thirteen weighed 185 lbs. He took 250 grams of levulose without glycosuria. It, however, gave him marked urticaria and the parents objected to further tests of his tolerance. He was under observation for a year, his carbohydrate intake being decreased and being fed on extract of the posterior lobe of the pituitary. His temperature reactions were marked. Previous to treatment, his average temperature was about 96°. With proper doses of the extract it would become normal, only to decrease when it was discontinued. The boy lost 60 lb. in weight in about six months. His temperature became normal and his mental activity became greatly increased, so that the following year he was first in his class in school, whereas before he had been distinctly backward.

Dr. DANA asked Dr. Niles whether the injection of extract of anterior or posterior lobes would help with diagnosis. Cushing injected anterior lobe and if there was a thermic response he considered it diagnostic.

Dr. NILES said Cushing thought that injections were of very great value and his own experience corroborated it.

Dr. THACHER said that some twenty years ago, in the days before the functions of the pituitary body were understood, when the endocrine glands had not been properly introduced to the profession, and the Roentgen rays were not yet discovered, he had a patient who probably belonged to the group described by Dr. Dana. The man was extremely somnolent and fell asleep several times in Dr. Thacher's office. He was a civil engineer and still at work. He had also severe pains in his head. From these and certain eye symptoms Dr. Thacher concluded that he had an interpeduncular tumor. Dr. Starr came to the same conclusion. Dr. Hartley advised an attempt at removal by operation, but the man refused. Later Dr. Thacher heard indirectly that the trouble proved to be the morphine habit. Some years later, however, the man's brother, who was a physician, reported that the patient had died, and an autopsy was held. An interpeduncular tumor was found.

Dr. DANA, in reply to Dr. Conner, said that he did

not feel at all sure of this subject himself. He only knew that for six years he had been continually examining and comparing the records of blood examinations in people that had presented the phenomena that suggested pituitary or thyroid disease. Dr. Kaplan had always insisted that there were certain rather characteristic forms of blood change and he had come to think there was something in it. For example, in a case of hypothyroidism in a boy of seventeen, six blood counts during the month of March showed an average of white blood cells, 11,600, neutrophils 47, large and small lymphocytes 44, eosinophiles 4. After two months treatment with thyroid extract, and after eight months treatment with marked clinical improvement, the formula was—white blood cells 10,500, neutrophils 69, large and small lymphocytes 35, eosinophiles 5. In reply to Dr. Longcope, Dr. Dana said that 700 grams of glucose injected gave no trace of sugar in the blood; 500 grams was taken by mouth. In reply to Dr. Brannan, Dr. Dana said that if the case mentioned by Dr. Abbe had been petit mal, there would have been other attacks. Cushing had reported improvements in cases with anterior lobe lesions, but they were cases of hypophyseal tumor.

Case of Acute Omental Torsion.—Dr. CHARLES H. PECK made this presentation. He stated that in October, 1915, a patient, forty-eight years of age, known to him for fifteen years, came to his office, complaining of right-sided abdominal pain at the level of the umbilicus. It had been present for about two days, had increased slightly, and was associated with some tenderness, which seemed superficial. The patient did not feel especially ill, except for the pain. His temperature and pulse were normal. Pressure over the appendix region elicited no tenderness, nor did pressure over the gall-bladder region. There was slight rigidity at the site of the maximal tenderness, which seemed partly voluntary. According to Dr. Peck's knowledge, the patient had always been well, had led a regular life, with regular exercise, lately horseback riding. There was no history of indigestion, and no symptoms suggestive of appendicitis. Years before he had a supposed inguinal hernia, but if this had existed, it had undergone spontaneous cure. Considering the patient's known good health, Dr. Peck thought it probable that the pain was some superficial process in the abdominal muscles, perhaps induced by riding. The patient was told to go home, keep quiet, and have the family physician report on the symptoms. At 3.30 A.M. the following morning, the physician reported great increase in the pain, tenderness, and rigidity. When examined at 9 A.M. that morning, the tenderness and rigidity had greatly increased and had spread to the right lower quadrant. There was no elevation of temperature or pulse and no vomiting. A provisional diagnosis of acute perforating appendicitis was made and the patient was removed to Roosevelt Hospital for operation, which was performed at 11.30 A.M. Examination showed a diminutive, atrophied appendix, with no acute process. It was necessary to search for some other explanation of the symptoms. The incision was enlarged and, sweeping the hand upward, a rather hard, irregular mass was felt within, which, in being drawn downward, proved to be a mass of strangulated omentum which had undergone torsion of its pedicle. This was clamped off above the site of the torsion and removed. It consisted of about the middle third of the entire omentum. The portion to the left was entirely normal; that to the right somewhat hypertrophied, and adherent in places along the ascending colon and lateral parietes. The defect caused by the removal of the twisted portion was closed by suturing together the lateral edges of the remaining portion of the omentum. Some veil-like adhesions between the lateral abdominal wall and the ascending colon and cecum were the only other anomaly found. These did not have the appearance of having been caused by any pre-existing acute inflammatory condition. The omentum had no attachment in the region of either inguinal ring, and could have borne no relation to a possible pre-existing hernia. No cause for the torsion could be demonstrated, except that the central twisted portion gave the impression of having been tongue-like in form, partly separated, perhaps, from the lateral portion, before torsion occurred. The abdomen was closed without drainage, and an uneventful recovery occurred. Other cases reported from time to time were—by Dr. Peck, in the *MEDICAL RECORD* of March 3, 1909, a case of torsion of the whole omentum, with beginning gangrene, in which the pre-operative diagnosis was that of an infected pelvic cyst. This

patient had a hernia, but the sac was empty at time of operation, and the twisted omentum was not connected with it. The whole omentum was involved. In 1909, in the *Annals of Surgery*, Wiener reported seven cases, including one of his own. In 1903 Blake reported a case with hernia present. In 1904, Studder reported a case of torsion of the entire omentum, in which hernia had been present. He stated that only two cases had been reported, not associated with hernia. The condition was one of sufficient rarity to deserve report, and added one more condition to be considered as a cause of acute abdominal symptoms. The case presented to-night should be classed as one not associated with hernia.

Dr. MEARA asked were there adhesions to the parietal peritoneum, and was there very much rigidity when the parietal peritoneum was not involved?

Dr. PECK said that in this case there was rigidity, due to acute plastic peritonitis.

Dr. CONNER asked if there was beginning fresh peritonitis.

Dr. PECK said yes; what one would get around strangulated omentum.

Dr. ABBE asked if the patient was obese.

Dr. PECK said no; not especially so. He was in good condition and had had excellent health, with no suggestion of abdominal trouble.

Dr. CONNER asked if the twist was a single complete one.

Dr. PECK said the pathologist had thought there were two turns.

Dr. THACHER asked how that could be if it was so adherent.

Dr. PECK said he thought the adhesions came after the shutting off of the circulation. The twist caused little pain and began to tighten up before he saw the patient. After the circulation was shut off the early stages of gangrene commenced.

Dr. THACHER then asked if the condition could be clinically recognized.

Dr. CONNER said that nothing but peristaltic movement could have caused the twist.

Dr. PECK said the diagnosis was made of acute appendicitis. In his first case there was a mass in the cul-de-sac behind the uterus. They believed that an infected pelvic cyst existed, and found the whole omentum twisted. The diagnosis had seldom been made before opening the abdomen. Only seven cases were reported before 1900. In this case the lateral peritoneal adhesions were a little abnormal, more like an exaggerated Jackson's veil. He first opened a part where the peritoneum was not free. The right border was not strangulated. He thought the omentum must have been three-leaf shaped, and the central portion was tongue-like before the torsion occurred.

AMERICAN ASSOCIATION FOR STUDY AND PREVENTION OF INFANT MORTALITY.

(Continued from Vol. 88, p. 1112.)

Wages and Employment as Factors in Infant Mortality.—Mr. SHERMAN C. KINGSLEY of Chicago drew attention to the fact that districts with the largest measure of poverty presented a higher mortality from all causes than did localities better circumstanced. While it was difficult to assess baby deaths definitely against low income poverty involved housing, overcrowding, quality and amount of food, sunlight, air, and who'some leisure for mothers, he pointed out that infant welfare work had many aspects in common with the early anti-tuberculosis crusade, and that the achievements of the former were the result largely of overcoming the difficulties of circumstance and environment. The correction had come through wisdom and advice, the gifts of the community, communicated to mother and child by the doctor and nurse. Deep-seated and obstinate difficulties still remaining, however, were those due to inadequate wages. With the baby, as with communities, life and health were purchasable; figures showed that babies living in one room had less than half the chance of those living in four; the infant whose father made less than ten dollars per week had about half the chance of life of the one whose father earned twice the amount. Life saving advice to the mother must be accompanied by an industrial order which gave a living wage to the father.

Maternity Insurance.—Dr. LEE K. FRANKEL of the Metropolitan Life Insurance Company, New York City,

presented an historical account of the development of organized protection for motherhood which showed that from the thirteenth century provision either in the home or in hospital was made under the auspices of philanthropic agencies for the care of indigent women in childbirth. Changed industrial conditions had necessitated legislation protecting women working prior and subsequent to maternity. In practically all European countries legislation had been enacted which forbade women to work for from two to six weeks before and after confinement. In the United States in only four States—New York, Vermont, Massachusetts, and Connecticut. The next logical step to be taken in such compulsory legislation was the development of a scheme of insurance for the lying-in period to replace the wages lost. Such schemes also had been organized in nearly every European country. In Italy alone had the insurance plan developed as a distinctly maternity insurance to which both employee and employer contributed. In other countries insurance against maternity was a phase of general sickness insurance, the dues being paid by all members of the scheme. Under a sickness insurance scheme in which practically all of the working element were members maternity benefits were possible for from four to six weeks, medical care and medicine at approximately from $\frac{1}{2}$ to $1\frac{1}{2}$ per cent. of the wages. A general sickness insurance scheme rather than a strictly maternity system the author thought a wiser plan, were such to be developed in the United States.

To What Extent May the Mother Substitute Proprietary Preparations for the Advice of a Physician?—Dr. CARL L. ALSBERG of Washington, D. C., regarded the question as of vital interest to the mother, the physician, the welfare worker, the dealer, State and Federal officials. The mother in giving proprietary remedies was governed by false ideas of economy and convenience, and the truth should be presented to her by all possible means. The physician had a public and professional duty in the education of the public upon this vital question. The dealer was concerned solely from the business standpoint, and the solution was said to lie in an educated public opinion.

Infant-Saving Activities.—At the annual business meeting held Thursday morning reports were received from affiliated societies. Through its affiliated membership the Association was in touch with baby-saving activities in seventy-one cities, representing twenty-eight States, the District of Columbia, Canada and the Philippine Islands. Among the activities covered were prenatal care; infant feeding conferences; milk stations; instruction of mothers in care of babies, well and sick; hospitals for babies; care of homeless babies; social service work in connection with hospital care of mothers and babies; visiting nursing, town and country; city and State Departments of Health.

The Value of Negative Genetics.—Prof. E. G. CONKLIN of Princeton University in answer to the query "How the number of births of children receiving a faulty heritage from their parents may be reduced," said that theoretically, the number might be slightly reduced by segregation or sterilization of the parents; practically, this could be applied only to the most defective individuals who were usually under the care or duress of the State, but it would not greatly reduce the number of defective children. Many such children born of normal parents still carried the taint in their blood; if such persons could be prevented from leaving offspring, a much larger reduction in the number of defective children would result. In many defective children, born of apparently normal lines, the defects might be traced to adverse environment, but in many cases their cause was wholly unknown. If the methods of animal and plant breeders could be rigidly applied to man, there was no doubt that a great improvement would be effected in the human race, but for many reasons these methods could not be closely followed.

Mr. HOMER FOLKS said that while in New York State there was a law looking toward the sterilization of the undeniably defective, it had not been urged by the social workers of the State and had remained a dead letter. He thought it the consensus of opinion among social workers in New York that the segregation of the mentally deficient should be brought about.

Dr. CHARLOTTE ABBEY of Philadelphia believed that the fact that 30 per cent. of normal parents bore defective children was due to lack of responsibility and ignorance of the laws of nature. When teaching emphasized the fact that the act which brought a child

into the world should be kept sacred, as nature intended, children would be well born.

Professor CONKLIN, in closing, said that undoubtedly the best method of the prevention of reproduction by the seriously defective was in one of the two methods suggested. Segregation would probably be less offensive to the public mind and more readily enforced than sterilization and was in large measure being done. The segregation of none but the dependent class could be brought about, but this could and ought to be done. Coming now to the positive side of eugenics, he said it was probable that much more could be done than on the negative side. The rate of breeding among the seriously defective was not very high. On the other hand, the great danger was that the good stock would disappear; the good heredity lines were running out. A campaign of education was needed, emphasizing to every man and woman that they lived not unto themselves; that their most important duty was to leave in the world wholesome, happy children who would perpetuate their ideals. The saddest thing he knew was to see splendid families from which our great men had come disappearing. The maxim is sometimes heard, "As rare as a dead mule or a Quaker baby," and certainly the fine stocks were running out in many places. If the reproduction of the best were prevented and the reproduction of the worst allowed the race was doomed.

The Problem of Prenatal Life and Influences Which May Favorably Affect This Period of the Child's Growth.

—Mrs. MAX WEST, of the Federal Children's Bureau, Washington, D. C., said it had been abundantly demonstrated that the proper and adequate care of prospective mothers decidedly increased the probability that the babies of such mothers would be born healthy and normal. The problem is first one of education, for until a sufficient proportion of the "effective public" appreciated the importance to the race of the prenatal period, it would be needless to look for widespread work of this nature. An important function of this Association should be the reporting from time to time upon the most practical working methods of giving prenatal care and of popularizing the work. Medical care, though conspicuously important, could produce only a part of the desired result since the social conditions surrounding women at this time very largely determined their welfare.

Preparation for Motherhood.—Dr. FLORENCE H. RICHARDS, Medical Director of the William Penn High School for Girls, Philadelphia, said that if it was true that "the women held the destiny of the nation" it behooved us to prepare our girls to be good wives, mothers, and home makers. This knowledge came by careful training which was given by but few parents to their growing girls, either because of ignorance or of false modesty. Of necessity, therefore, it must be done in the higher schools by women physicians able to speak with authority. A broad course in eugenics for girls should include a study of the family and the home and their value to the State; home nursing, a consideration of adolescence, marriage, reproduction (from the biological standpoint), care of the baby, the racial poisons, prostitution, etc. Girls receiving such a course of study would realize more fully the sacredness and responsibility of marriage and their duty to the next generation.

Dr. GREGORY of Philadelphia said the well-trained biologist was needed to give to girls and mothers the information outlined by Dr. Richards. Special stress should be laid upon the importance of the right attitude toward right. It was beautiful to watch the development of a flower, but the attitude toward human life had been abnormal, and that which was the highest and most beautiful of all was looked upon as something to be ashamed of. Mothers, as well as daughters, were capable of correct training in this respect, and with this training given to mothers much would have been gained without waiting for the next generation.

Are Babies Worth Saving? Infant Welfare Work: Its Progress, Opportunities, and Agencies.—Mr. HOMER FOLKS of New York delivered the President's address. He said the only contribution he might hope to make to the meeting was an attempt to interpret some phases of the work of the Association to the general public. Being one of that general public, he might, perhaps, sense some of its difficulties more clearly than the professional members, considering the matter from the layman's point of view under (1) the underlying pur-

poses of infant welfare work; (2) the largeness of opportunity; (3) agencies upon which the chief reliance must be placed. Under the first heading he found the outstanding fact to be that the work was preventive rather than remedial. In a very few years the infant welfare movement had changed from the dealing with the few for curative purposes to dealing with the multitude for preventive purposes. From every point of view infant welfare must be regarded as raising the level at which the struggle for existence occurred, and not simply as a concession to humanitarian instincts. From the point of view of the largeness of opportunity great encouragement was found from the history of recent years that infantile illness and mortality were preventable with relatively little effort and expense. Compared with other large public health movements the reduction of infant mortality was simplicity itself. The New York State Health Department stated that there were about 300,000 deaths per annum in the United States among infants under one year of age and that 150,000 of these were preventable. For this work elaborate institutions were not required. The need was chiefly for plenty of paper, printer's ink, and trained nurses. To one of his associates he was indebted for the suggestion that printer's ink, rightly and continuously applied, would save many babies. Baby saving was the bargain counter of philanthropy. Infant welfare work was the great opportunity of the moment to do something in which everybody must believe. Just how much could be done was uncertain because of many factors, chief among which was the lack of vital statistics. Concerning the agencies for this work, he found that the bulk of effort was being done by private initiative, in many cases some public aid having been received; with the tendency toward the transference of the work to public responsibility. It seemed to him that the work was clearly a public one. Public health generally was certainly a public function, and infant welfare an integral part of the public health problem.

The Possible Reduction of Mortality Among Subnormal Institutional Babies.—Dr. S. JOSEPHINE BAKER, Director of the Bureau of Hygiene of the Department of Health of the city of New York, said that her paper was a combined experimental study of the Bureau of Child Hygiene of the Department of Health of New York, the Child Helping Department of the Russell Sage Foundation, and the New York Foundling Hospital. The high mortality of infants in so-called "foundling asylums" was well known, but in properly supervised placing-out systems this mortality had been reduced. Available statistics of the relative value of institutional versus placing-out care had been generally founded upon a mass consideration of all infants in the institution and a broadly selected group of the better physical type of infants placed out. The present study was based upon the placing out of the physically poorest type of institutional infant. These included the premature infants, severe cases of marasmus, and other nutritional disorders. The selected group included only the type in which the institutional mortality had previously been approximately 100 per cent. The results of this procedure showed a mortality rate decreased to 52 per cent. The experiments covered a period of sixteen months.

Institutions as Fester Mothers for Infants.—Dr. ALFRED F. HESS, New York City, stated that the sweeping denunciation of the institutional care of infants was not justified. If the administration were poor the babies would suffer whether in homes or in asylums, and there was nothing inherent in either system which led to health or to disease. Dr. Hess said that at present there was no established statistical basis of approach to the questions as there was no approved method of calculating the death rate in an institution. The Association, he believed, would perform a valuable service if it devised a method having the approval of experts. It would then become possible to carry out comparative investigations of this important subject in various large cities of the United States.

A Study of Selected Communities Where Infant Welfare Nursing Is Done on a Small Scale.—Miss BESSIE S. LELACHEUR of New York said that no large city in the United States could consider itself up to date without a well-defined program of infant welfare work. There were also countless smaller communities with needs as great and infant mortality greater. The report considered the work in 215 small towns and villages where many were doing infant welfare work and general nursing. She said that the

general nurses were eagerly asking for suggestions upon effective infant welfare work to be fitted into their daily duties and responsibilities. The committee therefore concluded that a suggestive and flexible program should be worked out for the general nurse in which the health of the family rather than that of the individual became the responsibility of the nurse.

A Community Program of Public Health Nursing and Social Service as Worked Out in Fall River, Mass., and in Dayton, Ohio.—Mr. RICHARD P. BORDEN of Fall River thought that social agencies should be co-ordinated so that each would work in its special department and all work together. Health was fundamental in community efficiency. Hospitals were expensive, and it paid to avoid the necessity of hospital care. Therefore visiting nurses were necessary adjuncts of hospitals. Sources of accident and disease were ignorance and improper methods of living. Settlement houses taught the family that it was cheaper to prevent disease than to cure it, and in consequence hospital costs were reduced. Day nurseries, children's societies, and other social organizations were directly related to the hospital and its kindred agencies. While it was valuable to preserve entities of social organizations, business and benevolence should combine.

Miss ELIZABETH GORDON Fox of Washington, D. C., believed that the old plan of specialization in public health nursing was wasteful, confusing, and inefficient. In 1914, the Visiting Nurse Association, the Tuberculosis Society, and the Department of Health of the city of Dayton, Ohio, "pooled" their interests and combined the three staffs of nurses into one under one superintendent, in one headquarters. While each governing body retained its own autonomy and raised its own budget, the work of the three was administered as a unit. The nursing specialties were eliminated, the city was divided into small districts, one nurse to a district, and each nurse did all kinds of nursing in her own district. The infant welfare work was greatly increased in quantity and quality as a result of this plan of centralization and generalization. The infant mortality rate fell from 133 during the four summer months of 1913 to eighty-five during the same period of 1914. This was felt to be largely due to the efficiency of the new plan of administration.

Dr. H. J. GERSTENBERGER said that which was most desirable to be accomplished was the adoption of a plan which would bring the best results to the individual and to the community. He had believed for many years that the best results in public health and social work were to be secured by placing all the work of a district in the hands of one worker who should be supervised and directed by a physician who upon the basis of knowledge and common sense was competent to so supervise and direct.

Miss MARIE PHELAN of Chicago said that the infant welfare nurse must be interested in the family and in the sanitary conditions of the home that she might create a proper environment for the baby. It was through her influence that the father was referred to the tuberculosis clinic and the nurse welcomed to give information concerning the conditions of the home. She thought that the question of more than one nurse coming into the home had been greatly overestimated; in reality there was little fear of overlapping. In only two families in eighteen districts were the infant welfare nurse and the district nurse visiting at the same time. She said but few nurses were capable, mentally and physically, to look after every branch of nursing.

Dr. S. JOSEPHINE BAKER said she took issue absolutely with Mr. Borden that the function of the public health nurse was nursing the sick. She said those who heard Mr. Folks' address could not but be impressed with the emphasis he had placed upon the primary function of the Association being the prevention of infant morbidity. Just so far as that note was emphasized would there be success. The nurture of the well had its place in contradistinction to the nursing of the sick. If nurses were going to deal only with the sick baby their ideas would be so diverted from the main purpose that the well baby was going to stand in the background. In municipal work when nurses had tried to keep the well baby well the mortality had dropped sharply. The public health nurse from the point of view of the Department of Health was a sanitary officer with the education of a nurse. She was a teacher, but not like the district nurse, a nurse of the sick. She thought there was danger of overspecialization, but not necessarily, if ideals were kept clearly in mind.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF SOUTH CAROLINA.

June, 1915.

(Concluded from page 1078, Vol. 88.)

GYNECOLOGY.

1. Mention two common causes of hemorrhage from the non-pregnant uterus. How would you differentiate them?
2. Give the causes and treatment of retrodisplacements of the uterus.
3. Differentiate salpingitis in the right side from appendicitis.
4. Describe an operation for removal of the uterus. When is it indicated?
5. Give the causes and treatment of amenorrhea.

SURGERY.

1. Differentiate between acute synovitis of knee joint and acute osteomyelitis about joint, and give treatment of each.
2. In excision of knee joint give details of operation and after treatment. Outline flap used.
3. Describe and outline various flaps used in amputating in different regions from ankle joint to middle of thigh.
4. Make a preparative diagnosis in a woman suffering with tenderness in right side of abdomen from ribs to pelvis, with occasional paroxysms of pain; daily slight rise of fever with albumin in urine.
5. Give indications for enucleating an eyeball and describe an enucleation.
6. Describe the anesthetic state from ether and chloroform.
7. Operate for necrosis of shaft of tibia. If you found all of a section of the bone destroyed and the periosteum intact what would you do?
8. What organs and regions does a right rectus incision allow access to. Describe the technique of making the incision and the closing of it.
9. Give the varieties of hemorrhoids and give in detail the operation of removal of internal hemorrhoids by both suture and clamp and cautery methods.
10. Treat fracture, both impacted and unimpacted, in a very old person.

PEDIATRICS.

1. How would you diagnose and treat flatulent colic in an infant? What food constituent is the usual cause of this condition?
2. Give the causes, consequences and treatment of otitis media.
3. What diseases may diphtheria simulate and how would you differentiate them?
4. Give the symptoms and treatment of pertussis. What is its most serious complication?
5. Give the symptoms and treatment of acute anterior poliomyelitis.

URINALYSIS MICROSCOPY, TOXICOLOGY, AND MEDICAL JURISPRUDENCE.

1. In the examination of urine, how would you differentiate precipitates of urates, earthy phosphates and albumin?
2. Name several drugs that render the urine alkaline; give their indications and methods of administration. What class of acids would you give to acidify alkaline urine?
3. What casts are frequently found in albuminous urine and what do they denote?
4. What is hematuria? What conditions cause it and how does it appear microscopically?
5. Name four conditions in the physical organism which would modify the effects of poisonous drugs.
6. What two remedies are especially indicated in chronic lead poisoning? Describe the action in said condition.
7. How would you differentiate between true poisoning and diseases which simulate poisoning?
8. In examining vomited matter or a stomach suspected to contain phosphorus, what simple methods would show its presence?
9. How would you distinguish between intentional and accidental abortion?

10. What are the signs of death?
HYGIENE.

1. Discuss briefly artificial heating in its relation to ventilation.
2. What are the general rules for ventilating a room by providing inlets and outlets, as to size, location and number?
3. What are the sources of water supply?
4. Discuss milk as a factor in the spread of disease.
5. What diseases are transmitted by mosquitos?
6. (a) Describe the mosquitos causing malaria. (b) What measures would you adopt to destroy them?
7. (a) Discuss room disinfection. (b) Municipal quarantine.
8. What diseases threaten soldiers and civilians in the tropics?
9. If you were a surgeon of a post or camp, what measures would you adopt to prevent disease among the troops?
10. How would you deal with an epidemic of cerebro-spinal meningitis?

BACTERIOLOGY AND PATHOLOGY.

1. How do bacteria multiply? What is meant by the terms aerobic and anaerobic bacteria?
2. What are the staining peculiarities of the *Bacillus tuberculosis*?
3. Describe the *Diplococcus intracellularis*. Where is the organism found and how is it identified?
4. What are the causes, results and terminations of thrombosis?
5. Describe the microscopical structure of sarcomata and carcinomata and give the usual mode of extension of each.

ANSWERS.

GYNECOLOGY.

1. Two common causes of hemorrhage from the non-pregnant uterus are endometritis and adenocarcinoma. To differentiate these, microscopic examination of the scrapings may be necessary. The following table (from Dudley's *Gynecology*) may help:

GLANDULAR HYPERTROPHIC ENDOMETRITIS.	GLANDULAR HYPERPLASTIC ENDOMETRITIS.	ADENOCARCINOMA
1. Glands increased in size but not in number.	1. Glands increased in size and number.	1. Glands very greatly increased in size and number.
2. No proliferation of gland epithelium.	2. Proliferation of gland epithelium.	2. Very great proliferation of gland epithelium.
3. Gland structures nearly or quite typical in outline.	3. Gland structures more tortuous in outline.	3. Gland structures very atypical in outline.
4. Hypertrophied epithelium confined within the limits of the tunica propria.	4. Proliferation confined within the limits of the tunica propria.	4. The proliferating gland epithelium has broken through the tunica propria and is in direct contact with interglandular connective tissue, and is multiplying in an atypical manner.
5. Gland tissue does not invade muscularis deeply.	5. Gland tissue does not invade muscularis very deeply.	5. Gland tissue may very deeply invade muscularis.
6. Can trace tortuous glands.	6. Can trace tortuous glands.	6. Glandular labyrinth; can not trace tortuous and atypical gland.
7. Stroma normal in quantity.	7. Stroma decreased in quantity, but clearly defined from glands.	7. Great rarefaction of stroma, so that glands touch one another. Glands have broken through basement membrane and invaded intraglandular spaces and muscularis.

2. RETROFLEXION. *Etiology*: Tight lacing and tight clothing; congenital conditions; pressure by tumors; metritis and parametritis with adhesions; atonic conditions of the uterus following labor, and the conditions that cause retroversion. *Treatment*: If there are no adhesions, the flexion should be corrected by digital manipulation and a pessary introduced; hysteropexy may be necessary.

RETROVERSION.—*Etiology*: Relaxation of uterine ligaments; increased weight of fundus; subinvolution; ovarian or other tumor pressing on front of uterus; distended bladder; peritonitis or cystitis; prolonged

dorsal decubitus and tight bandaging in the puerperium. *Treatment:* Remove the cause, if possible; replace the uterus and keep it in position by pessaries, tampons, and knee-chest position; pelvic massage and vaginal douches; proper hygiene, particular attention being paid to the bowels, clothing, and exercise. *Curative treatment:* The choice lies between ventral suspension of the uterus and shortening of the round ligaments.

3.—

APPENDICITIS.

1. No previous local disturbances.
2. Chill usually absent.
3. Pain in right iliac region, sudden onset, acute, and not radiating to thighs.
4. Fever of variable degree.
5. Muscular rigidity on right side of the abdomen.
6. Inflammatory exudate about appendix three to five days after onset of symptoms.
7. Vaginal examination is rarely painful in appendicitis.

SALPINGITIS.

1. Genitourinary functions previously disturbed. Usually a history of gonorrheal or puerperal infection.
2. Chill may precede fever.
3. Gradual onset, pain dull, continuous, and radiating.
4. Fever often entirely absent.
5. No muscular rigidity unless complicated by peritonitis.
6. Inflammatory exudate in the pelvis felt by vaginal examination at the onset of the symptoms.
7. Always painful in tuboovarian disease.

—(Findley.)

4. *"Indications for Hysterectomy.*—Hysterectomy is indicated if the disease is limited to the uterus. Such limitation will be inferred: 1. By the normal mobility of the uterus. 2. By the absence of any enlargement of the lymphatic glands in the parametria. 3. By the absence of the disease on the vaginal walls. Enlargement of the glands is evidence that the disease has extended beyond the uterus. This does not positively contraindicate hysterectomy, but renders the prognosis less favorable. Whether enlarged or not the glands should, if practicable, be removed. Extension of cancer to the vaginal walls, if slight, does not definitely contraindicate hysterectomy, provided the diseased portion of the vagina can be removed with the uterus. Extensive involvement of the vagina and fixation of the uterus in surrounding cancer contraindicate the operation.

"When the disease has passed beyond the hope of radical cure, but not beyond the limits of palliative hysterectomy, hysterectomy is sometimes performed for the temporary relief of symptoms; its benefits, however, are not usually sufficient to overbalance its dangers."—(Dudley's *Gynecology*.)

Abdominal hysterectomy.—"The patient must be carefully prepared as for any other abdominal operation, but in addition the pubes and vulva must be shaved and thoroughly purified; the vagina should be douched for some days previously, and an antiseptic dressing worn, and if need be the uterine canal should be curetted and disinfected with some powerful antiseptic.

"After anesthesia has been induced the Trendelenburg position is adopted, and an incision of suitable length made in the median line. The parts are then carefully explored, and if no adhesions exist an abdominal cloth is packed in over the intestines in order to protect and keep them from exposure and injury. If adhesions to omentum or gut are present they must be carefully divided; it is, of course, most desirable that a complete peritoneal covering should be secured for any adherent organs; omental grafts may be sometimes useful in this direction. The broad ligaments are then examined, and a decision made as to whether or not the ovaries and tubes are to be saved.

"A pedicle needle carrying a sufficient length of well-boiled silk is carried through the round ligament so as to secure the ovarian artery and veins, and tied as far away from the uterus as possible. A broad ligament clamp may then be placed in position close to the uterus, so as to prevent venous regurgitation, and the broad ligament is divided half-way down. It is often possible and desirable

to pick up the divided end of the ovarian artery on the face of this section and secure it separately, while the little artery which accompanies the round ligament should also be carefully secured. The ovarian artery on the other side is next dealt with in a similar fashion. A transverse cut is now made across the front of the uterus, involving merely the serous membrane and connecting the two ends of the incisions in the broad ligaments; the peritoneum below this transverse cut is detached, together with the bladder, from the cervix, and the intraligamentary space is thereby opened up on either side. In this will be found the uterine vessels, and it may be possible to see and isolate the uterine artery before securing it by ligature. Care must be taken in this part of the operation to keep close to the uterus, as the ureter comes forward from behind under the uterine artery to reach the bladder, lying about the level of the os internum. The uterine vessels are in this way carefully secured and divided.

"The uterus is now merely held by the connection between the vagina and cervix and the peritoneal reflection in Douglas' pouch. If a supravaginal operation will suffice, the surgeon cuts across the neck of the uterus in such a way as to fashion two flaps, and finally the peritoneum behind is divided. A few small vessels will probably need to be secured on the face of the uterine stump. This having been effected, the uterine flaps are stitched carefully together so as to bury the open cervical canal; the uterine stump is then covered in by uniting the divided portions of peritoneum. This line of sutures is carried up on either side so as to secure the two layers of the broad ligament; the final result is that the pelvic floor is covered in by a continuous layer of peritoneum, showing a sutured incision which runs transversely from one side to the other. The usual peritoneal toilette follows, and the abdomen is generally closed entirely, no drainage being required."—(Rose and Carless' *Surgery*.)

5. AMENORRHEA is *physiological*: Before puberty, during pregnancy and early lactation, and after the menopause. It may also be due to: Absence or imperfect development of the generative organs; also to stenosis, obstructions, or atresia of the genital tract; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold, and various emotional causes. *Treatment* consists in: (1) Removing the cause, if possible; (2) general treatment by means of proper hygiene, rest, diet, bathing, attention to the bowels, exercise, etc.; (3) drugs reputed to be emmenagogues, such as iron, manganese, aloes, strychnine, apiol, oxalic acid, savine, rue, and tansy.

SURGERY.

1. In *acute synovitis of the knee-joint*, the joint is swollen, tender, hot, and painful; there is a bulging on either side of the patella, and the patella is floated away from the condyles; fluctuation is felt from side to side, and the patella may be made to tap on the femur; the joint is fixed in a slightly flexed position, and movement is resisted by the patient.

In *acute osteomyelitis*, the swelling is not localized to the limits of the synovial membrane of the joint, as is the case in acute synovitis; fluctuation, if present, is not so pronounced nor is it "from side to side" behind the patella; pain is more severe, and symptoms of toxemia may be present; rigors and high fever are noticed.

In *synovitis of the knee-joint* the treatment consists in immobilization of the joint, bandaging, application of lead and laudanum lotion, ice is of use in the very early stages, later on (if pain is present) hot applications are of service; if the tension is very great leeches or aspiration may be of benefit. Later on, massage and passive movements are serviceable.

In *acute osteomyelitis* treatment must be prompt; an incision must be made through the periosteum and the pus evacuated, the surface of the bone removed, and the cavity exposed, washed out, and drained.

2. *Excision of the knee-joint.*—"A semicircular incision is to be made, with the convexity downward, commencing at the side of one condyle of the femur and passing immediately above the tubercle of the tibia to a corresponding point on the opposite condyle. This incision divides the patellar ligament, and the patella is turned up in the flap; the crucial ligaments should then be cut across, and any remaining lateral attachments divided. The limb must now be forcibly flexed

and the knife carefully applied to the posterior part of the head of the tibia; a blunt pointed resection knife is best for this purpose. The articular surfaces are to be sawed off. The lower end of the thigh bone should first be removed; the division must be made accurately at right angles to the shaft of the femur, in the antero-posterior direction. A thin slice is next taken off the tibia; the section must be accurately at right angles to the shaft of the tibia. Care must be taken not to remove more of the bones than is absolutely necessary, especially in young subjects. If the patella is much diseased, it should be removed; if it is only slightly carious, it may be scraped or gouged out; if healthy, it should be left to consolidate and strengthen the joint. But the articular surface should be destroyed to favor firm union with the femur. To keep the bones in position they should be drilled obliquely at the anterior part, and secured by two strong sutures of catgut. If the wound is septic, wire sutures are the best. Before the wound is closed all hemorrhage must be thoroughly arrested. Ligatures must be applied to the articular arteries, if necessary. The patellar tendon should be stitched in place with catgut and the wound drained for one or two days by tubes or numerous strands of silkworm gut. The limb must be kept at perfect rest for the first few weeks; a narrow, properly padded splint extending from the hip to the heel, will meet all indications. It should be fixed in position by a flannel bandage above and below the knee, over which a firm plaster of Paris bandage must be applied. An interrupted plaster splint with connecting side irons allows free access to the joints for dressing and prevents soiling of the splint. The first dressings should be changed after 24 hours. After that the dry, antiseptic wool dressings should be used, which can be left untouched for two or three weeks."—(*Cyclopedia of Medicine and Surgery*.)

3. VARIOUS FLAPS USED IN AMPUTATIONS.—*Ordinary circular amputation:* The soft parts are divided by a series of circular cuts, retraction of the parts taking place between each circular sweep of the knife, so that they are cut partly through at different levels the sawed bone forming the apex of the funnel left upon the proximal end of the limb, and the skin margin the base, the distal part removed being cone shaped.

Cuff method of circular amputation: A circular division of the skin is made, which is turned over and upward upon itself as a cuff and, upon a level with this retracted cuff of skin and fascia, the muscles are divided to the bone, generally with one circular sweep of a long knife.

Modified circular amputation: Two equal flaps, composed of skin and fascia, of varying length, and having bases equal to one-half of the circumference of the limb at their upper ends, are cut and dissected up a short distance followed by a circular sweep of the knife through the retracted superficial muscles—and by a circular sweep at a higher level through the retracted deeper muscles—and completion of the operation as in the ordinary circular amputation.

Oval method of amputation: A modification of the circular method. The skin incision is in the form of an oval, with one of its ends more prolonged and pointed—the soft parts between skin and bone being divided by cutting from without inward—and the lips of the wound being sutured in a single line parallel with the long axis of the wound.

Racket method of amputation: A modification of the circular method. The same, in principle, as the oval amputation—with the addition of a longitudinal vertical cut prolonged from the apex of the oval forming the "handle of the racket"—thus giving a better exposure of joints without sacrifice of tissue and securing a better covering for the bone in the upper part of the wound.

Amputation by single flap of skin and muscles: A method of amputating whereby the stump is covered with a single flap derived from one aspect of a limb—and consists of skin, fascia, and muscles. Such an amputation involves the maximum sacrifice of bone.

Amputation by single flap of skin: The features of this operation are practically the same as those of the amputation by a single flap of skin and muscles, except that the covering here consists entirely of skin.

Amputation by equal flaps of skin and muscle: Coverings for the stump are gotten from two opposite aspects of the limb in the form of two flaps composed of all the soft parts covering the limb—having equal bases and lengths—and the allowance of skin being sufficiently in excess to well cover the muscles.

Amputation by equal flaps of skin: This operation is the same, in general contour and dimensions of the flaps, as the last—except that the covering here consists of skin only.

Amputation by unequal flaps of skin and muscles: Coverings are furnished by two flaps taken from opposite aspects of the limb—each flap having a base equal to one-half circumference of the limb at the saw line—and one flap having a length greater than the other. One flap usually furnishes one-third or two-thirds of the covering, and the opposite flap two-thirds or one-third—the longer flap generally coming from that aspect of the limb most thickly muscled. The flaps may bear any relation to each other in relative length—but the two flaps combined furnish a covering equivalent to $1\frac{1}{2}$ diameters of the limb at the saw line.

Amputation by unequal flaps of skin: Coverings are of skin and fascia alone and are furnished by the two opposite aspects of the limb, in the form of two flaps having equal bases and unequal lengths. This amputation is identical throughout with the amputation by equal flaps of skin, except as to the length of the flaps.

Amputation by unequal rectangular flaps of skin and muscles: The general method of performing this operation is similar, in principle, to that for amputation by unequal flaps of skin and muscles—with the exception that the flaps are rectangular (instead of rounded) and of special dimensions.

Elliptical method of amputation: This is not a distinct form of amputation. It may be considered a variety of the circular method (an oblique circular), or, equally, a variety of single flap amputation—and may be held in an intermediate position. It is circular, as to skin incision; and flap, as to its manner of covering the stump and in the suturing. The skin incision is in the form of an ellipse, or a lozenge, the upper part of the ellipse being upon one aspect of the limb and the lower part upon the opposite—the lateral limbs of the figure crossing the lateral aspects of the limb to be amputated. The idea of the ellipse is brought out by imagining the outline projected upon a flat surface.

Best methods of amputation about the leg: Oblique elliptical for the supramalleolar region. Large anterior and small posterior flaps for lower third, between supramalleolar region and lower limit of middle third. Large posterior and short anterior flaps for middle third. Large external flap for upper third. Bilateral hooded flap for "place of election," or upper part of upper third.

Best methods of amputation through the thigh: Shorter anterior and longer posterior flaps for transcondyloid region. Longer anterior and shorter posterior flaps for supracondyloid osteoplastic operation. Long anterior and short posterior flaps for thigh throughout, where the tissue is limited. Oblique Circular, or elliptical, method for lower third.—(From Bickham's *Operative Surgery*.)

4. The case is one of either pyelitis, pyelonephritis or beginning cholecystitis or stone in the kidney. In the case of the two latter the paroxysms of pain will increase an intensity, and in the case of cholecystitis the pain will radiate to the shoulder whereas in stone in the kidney it will radiate down the course of the ureter. Urinary examination and catheterization of the ureters will show if it is pyelitis or pyelonephritis.

5. The indications for enucleation of the eye are: "(1) Injuries of the ciliary region when the eye is completely blind, or the traumatism so extensive that the form of the eyeball cannot be preserved; (2) traumatic iridocyclitis, to prevent or cure sympathetic ophthalmia; severe pain in a blind eye; (4) iridocyclitis, phthisis bulbi, and glaucoma, when accompanied by severe pain or inflammatory symptoms, and when the eye is blind or is certain to become so; (5) malignant tumors, either intraocular or episcular, if they cannot be removed with retention of the eyeball; (6) anterior staphyloma, if the eye is blind, troublesome, and disfiguring; (7) panophthalmitis, after the suppurative stage is passed; (8) foreign bodies in the eye when they cannot be removed and cause irritation, or the eye is blind."

Enucleation of the eyeball is performed as follows: "A general anesthetic is generally given. After introduction of the speculum, the conjunctiva is divided all around the cornea, as close to its border as possible, and dissected back as far as the insertions of the recti muscles. A squint hook is passed beneath the tendon of the internal rectus, and the latter is divided with the strabismus scissors close to its insertion; then the other straight muscles are cut in the same way, together

with the subconjunctival connective tissue for some distance beyond the equator. The points of the scissors must always be directed toward the eyeball and the latter stripped as clean as possible to avoid any unnecessary removal of orbital tissue. Instead of commencing with a circumcorneal division of the conjunctiva, we may begin with a tenotomy of the internal rectus and then divide the conjunctiva as we pass from tendon to tendon. The hook is passed around the globe to make sure that the attachments of the muscles have been completely divided. The eyeball is then dislocated forward by pressing the speculum backward, and thus the optic nerve is put on the stretch. A pair of enucleation scissors, closed, are passed between sclera and conjunctiva, feeling for the optic nerve; they are withdrawn, slightly opened, and the nerve is divided close to the sclera. The eyeball is held between the thumb and index finger of the left hand, and the oblique muscles and other unsevered attachments are divided. The orbit is plugged for a few minutes to control hemorrhage, and the conjunctiva is usually closed with a single suture, which is passed through its edge at intervals and tied like the string of a pouch. The eye is bandaged and the patient kept in bed for a day." (May, *Diseases of the Eye*.)

6. *Ether anesthesia*: "During the first stage of anesthesia, which ends with the loss of consciousness, the pulse is accelerated, the pupils large and mobile, and a rather pleasant feeling of drowsiness, and tingling in the extremities, is experienced. Many patients breathe deeply, others hold their breath; in the latter instance all that need be done is to remove the cone for a moment. Cough is rarely annoying if the drop method be employed. With the onset of unconsciousness there is a short period of analgesia (primary anesthesia), during which brief operations may be performed. The second stage, or the stage of excitement, extends from the loss of consciousness to the loss of reflexes. Memory, volition, and intelligence are abolished, while laughing, shouting, and struggling may occur. Slight movements of the extremities should not be restrained unless they interfere with the anesthetist, as such often evokes greater struggling. The pulse is rapid, the pupils are dilated and react to light, and the muscles may be rigid or thrown into clonic contractions. At this time the breathing may be irregular or temporarily suspended. The face is congested, sometimes cyanotic, and often covered with perspiration. More or less frothy mucus is present in the mouth and throat, and sometimes it becomes excessive. During the third stage the breathing is deep and audible, the pulse full and regular, the muscles relaxed, and the corneal reflex abolished. Touching the cornea with the finger, however, may produce irritation, and it is much better simply to separate the lids and notice the presence or absence of flaccidity. The pupils are of moderate size and react to light. Dilated pupils failing to react to light indicate a dangerous degree of anesthesia. During this stage a transient roseolous rash may be noticed.

Chloroform anesthesia: "The phenomena of chloroform anesthesia are in the main similar to those of ether. The first and second stages are shorter, the vapor is more pleasant, and being less irritating than ether, not so much mucus is poured out. An excess of chloroform causes the patient to hold his breath, and if the inhaler is not withdrawn at this time, the patient may take a deep inspiration and get an overdose. This accident has resulted in death, and should be recalled when chloroforming crying children, and when a surgeon attempts to operate before the third stage is reached, thus causing the patient to breathe deeply. During the stage of muscular excitement, which is less marked than with ether, the respirations should be watched with great care. Chloroform vapor is not inflammable, but in the presence of a naked flame gives off irritating products (phosgene and hydrochloric acid), which, in a small room, may cause irritation of the eyes and respiratory passages. The third stage is characterized by quiet respirations which are often difficult to appreciate. The pulse is sluggish and feeble in contrast to the full and rapid pulse of ether. The pupil is moderately contracted unless the anesthesia is profound, when it dilates. As with ether, dilated pupils, failing to react to light, indicate a dangerous degree of anesthesia." (Stewart's *Manual of Surgery*.)

7. The treatment of central necrosis comprises free incisions for drainage, antiseptic dressing, frequent cleansing, rest, nourishing food, stimulants, and tonics.

When the sequestrum becomes loose the operation of sequestrectomy or necrotomy is performed, the extremity is drained of blood, an Esmarch band is applied, the bone is exposed by a longitudinal incision, the periosteum is reflected on each side, and the involucrum is broken through and the opening is enlarged with the chisel, gouge, and rongeur. The dead bone should be removed by sequestrum forceps, the cavity scraped by a sharp spoon, the lateral edges of the involucrum cut down until the cavity which formerly contained the sequestrum is very shallow, the wound is irrigated with hot salt solution, dried, painted with pure carbolic acid and then with alcohol, again irrigated with salt solution and firmly packed with iodoform gauze. Remove the Esmarch band, tie the vessels in the soft parts, suture the wound, and apply dressings. The simple removal of a sequestrum i.e., the operation of sequestrectomy, often fails to effect a cure, and even in the most satisfactory cases healing requires a very long time. . . . If the periosteum is found not to be infected, it may be stitched together at the gap where the bone has been removed, so that a periosteal cord exists between the two ends of the bone; and the soft parts above this may be closed. . . . The cavity that is left by the removal of a sequestrum and the chiseling of the walls of the involucrum, if large, may be filled by various methods more or less satisfactory. In some cases of widespread necrosis, due to diffuse infective osteoperiostitis, or to osteomyelitis, extensive resection or even amputation, may be necessary." (DaCosta's *Surgery*.)

8. A right rectus incision gives access to the gall bladder and ducts, duodenum, ascending colon, right kidney, ureter, liver, appendix, stomach. A vertical incision is made in the skin and fascia, about three inches long, and calculated to fall about three quarters of an inch internal to the outer border of the rectus; clamp vessels; retract overlying tissues, and expose the rectal sheath. Incise the anterior sheath of the rectus. Retract outwards the outer portion of the divided sheath of the rectus, so as to expose the outer border of the rectus muscle, and then retract the intact rectus muscle inward. Incise the posterior layer of the rectal sheath somewhat nearer the median line than in the case of the anterior layer. Or, in operating in the neighborhood of the deep epigastric artery, in order to avoid this vessel, the incision in the posterior layer may be made somewhat further outward than the incision through the anterior layer. The artery may, however, be readily ligated if in the way. In the same line as the division of the posterior layer of the rectal sheath, incise vertically the subjacent tissues which will consist of transversalis fascia, subperitoneal areolar tissue, and peritoneum, except below the simular fold of Douglas, below which line the posterior layer of the sheath itself consists of transversalis fascia alone, and the subjacent tissues consist of subperitoneal areolar tissue and peritoneum. Having accomplished the object of the operation, the structures are to be sutured in the following layers—peritoneum, subserous areolar tissue, and posterior layer of the rectal sheath, with interrupted or continuous catgut suture;—anterior layer of rectal sheath with interrupted gut sutures, which also pass partly through the rectus muscle (the displaced border of the rectus should also be sutured to the outer margin of the rectal sheath);—the fascia, with gut—and the skin with subcuticular silk, or interrupted silkworm gut sutures (or skin and fascia may be sutured together). (Bickham's *Operative Surgery*.)

9. The varieties of hemorrhoids are external, internal and mixed. The application of a ligature is the operation most often performed. The patient is placed in the Sims position, and after the field of operation has been rendered aseptic, the sphincter is divided. The rectum is irrigated with a mercuric chloride solution, 1:5,000. A needle carrying a ligature is passed through the base of the tumor. The thread is cut and the ligature is firmly tied on each side. At least two-thirds of the pile should be excised by the scissors. Iodoform gauze is inserted, and a T-bandage is applied. Morphine (gr. $\frac{1}{4}$) is then given. The bowels should be moved on the third day. (*Pocket Cyclopaedia*.)

Clamp and cautery. Radical treatment is advisable when there is much pain and bleeding. It must be ascertained first that the piles are not due to disease elsewhere, as cirrhosis or stricture, or to pregnancy. The bowels are emptied and the patient is placed in the lithotomy position. The sphincter is then dilated with two thumbs, to expose the piles, which are caught up

with ring forceps. A clamp is applied to the piles in turn, and they are removed by the cautery. The bowels are kept confined for five or six days, when castor oil is given. Very little pain and no bleeding follow this operation. Removal can be done by snipping the mucous membrane around the pile and ligaturing its base. Crushing is also done. (*Aids to Surgery.*)

10. In the case of very old persons the impacted fracture should be left impacted; the unimpacted fractures should be reduced; both fractures should be retained in position by a splint; but it is inadvisable to keep the patient for any length of time on his back. The dangers to old people are hypostatic pneumonia and the formation of bed sores; in the case of the impacted fracture the fixation should not be as thorough as is practised in young people, and massage may also be employed. Ambulant treatment should be instituted as early as possible.

PEDIATRICS.

1. *Flatulent colic* comes on rather suddenly; the child cries, and has a distended abdomen; the thighs are flexed on the abdomen, and the extremities may be cold. The treatment consists of hot applications to the abdomen, hot rectal and colonic irrigations with saline solution; the abdomen may be massaged with warm olive oil; a mixture containing chloral hydrate, sodium bicarbonate and peppermint water may be of service. It is frequently due to an excess of sugar in the food.

2. *Otitis media* generally occurs during one of the exanthematous diseases, or following diphtheria, tonsillitis or typhoid; it is due to a streptococcus. It may lead to perforation of the drum membrane, sinus thrombosis, or meningitis. The treatment consists of hot irrigations with saline solution, and early incision of drum membrane.

3. *Diphtheria* may simulate follicular tonsillitis and non-diphtheritic laryngitis or croup. In both cases a smear taken, and followed by proper culture and bacteriological examination will show absence of the Klebs-Loeffler bacillus. Further, the follicular tonsillitis is accompanied by a high fever (diphtheria is not); and in diphtheria the membrane is adherent to the underlying tissues, is removed with difficulty, bleeds when removed, and reforms; whereas in other similar conditions the membrane is easily removed, does not bleed, and does not form again.

4. In *pertussis* the incubation period is from 4 to 14 days, and is followed by a stage in which catarrhal symptoms, loss of appetite, fever, and restlessness are present. The paroxysms begin about the second week and consist of a number of short, spasmodic, expiratory coughs, succeeded by a long-drawn inspiration and a peculiar whoop, often terminating in vomiting. The eyes are suffused and the under lids are swollen and pinkish in color. The number of paroxysms may be very great, and this stage lasts from 3 to 4 weeks or longer. The symptoms then gradually ameliorate, and the stage of decline lasts 2 or 3 weeks longer. Convulsions, vomiting, bronchitis, and bronchopneumonia are the chief complications.

5. *Acute poliomyelitis* is a disease peculiar to childhood, and characterized by sudden paralysis of one or more limbs or of individual muscle-groups, and followed by rapid wasting of the affected parts, with reaction of degeneration and deformity. The onset is sudden and marked by fever, vomiting, convulsions, or even coma. Paralysis and atrophy of the muscles, with reactions of degeneration, then present themselves. It occurs usually during the first three years of life and most often during the summer months. It sometimes occurs in epidemics.

The treatment during the initial stage consists in rest in bed, restricted diet, fractional doses of calomel, and sponging, or small doses of phenacetin if the fever and nervous symptoms are marked. An ice-bag should be placed along the spine, or mild counterirritation to the spine by mustard plasters may be practised. After the acute symptoms have subsided, electricity and passive movements may be employed. Deformities may result and will require the application of mechanic apparatus or the performance of surgical operations for their correction. (*Pocket Cyclopaedia.*)

URANALYSIS MICROSCOPY, TOXICOLOGY, AND MEDICAL JURISPRUDENCE.

1. *Urates* cause a pinkish deposit, dissolve when the urine is warmed, and are generally amorphous.

Both *phosphates* and *albumin* are precipitated if the

urine is boiled; on the addition of a few drops of acetic acid the phosphates dissolve, but the albumin does not.

2. *Drugs that render the urine alkaline:* Potassium and lithium salts; they are given in cases of gout, lithemia, when diuretics are needed, in cases of strongly acid urine. They are given largely diluted with water. To *acidify alkaline urine*, one may use vegetable acids, benzoic acid, and salicylic acid.

3. *CASTS.* *Epithelial*, are found in desquamative nephritis. *Blood*, are found in acute renal hyperemia, acute nephritis, renal hematuria, and hemorrhagic infarction. *Pus*, in suppurative nephritis. *Bacterial*, in pyelonephritis, and suppurative nephritis. *Granular*, in chronic or degenerative nephritic processes. *Fatty*, in large white kidney, subacute or chronic nephritis with fatty degeneration. *Hyaline*, in all inflammatory conditions of the kidneys, also in circulatory disturbances (without organic change) of the kidneys. *Waxy*, in chronic nephritis.

4. *Hematuria* is the presence of blood in the urine when voided. It may be caused by: Infectious diseases, scurvy, purpura, pernicious anemia, congestion of the kidneys, traumatism or inflammation in any part of the urinary tract. On microscopical examination red blood corpuscles can be distinguished.

5. *The effects of poisonous drugs may be modified by:* Race, age, sex, weight, condition of health, and idiosyncrasy or tolerance.

6. In *lead poisoning*, magnesium sulphate is given: this converts the lead into the insoluble lead sulphate. Potassium iodide is also given, to aid in the elimination of such lead as is absorbed.

7. "In order to raise a valid inference in the mind of a medical attendant that poison has been administered to a patient, certain facts must be brought under his notice; and without the concurrence of at least two or more of these, the actuality of poisoning cannot be maintained. The sources of evidence in cases of suspected poisoning are the *symptoms*; the *post-mortem appearances*; *chemical analysis* of articles of food or drink, or of the body and the excretions; and *experiments upon animals*. The evidence derived from these sources, being compared with the known properties and effects of various poisons in authenticated cases, will enable the physician to form a correct opinion as to the probable administration or not of a poison. It is rarely that the symptoms exhibited during life do not afford some clue to the cause of illness; and most frequently the symptoms are all that the medical attendant has to guide him to a diagnosis of the nature of the case, during the lifetime of the patient. Sometimes, however, persons are found dead as the result of poison, concerning the manner of whose death nothing whatever can be learned; a suspicion of poisoning arising from the circumstances under which the corpse is found. Here the aid of chemical analysis ought invariably to be invoked; and fortunately in these cases the delay involved in making an analysis is of comparatively little moment. . . . The general conditions which should excite a suspicion of poisoning are the sudden onset of serious and increasingly alarming symptoms in a person previously in good health, especially if a prominent symptom be epigastric pain; or where there is complete prostration of the vital powers, a cadaverous expression of the countenance, an abundant perspiration, and speedy death. In all such cases the aid of the chemist is required, either to confirm well-founded, or to rebut ill-founded suspicions." (*Quain's Dictionary of Medicine.*)

8. If the vomited matters are agitated in the dark they are luminous.

9. "As natural abortion usually occurs at about the third or fourth month of pregnancy, and as this period is also the one at which a criminal operation is performed, the fact that the fetus comes away entire would indicate that abortion was due to natural causes, or at least not to instrumental violence. If, however, the fetus be expelled first and the ruptured membranes afterward, the conclusion would be that instruments had been used.

"If death follows within three days after abortion, the post-mortem examination will generally establish the fact that an abortion was committed. If several weeks, however, have elapsed, little or nothing will be learned by the autopsy, as the parts involved will have usually reassumed by that time their usual condition." (*Chapman's Medical Jurisprudence.*)

10. *Phenomena and signs of death*, are: The complete and permanent cessation of circulation and

respiration, rigor mortis, loss of body heat, pallor of the body, putrefaction.

HYGIENE.

1. "The principal methods of heating houses and rooms are: 1. Open fires. 2. Stoves. 3. Furnaces. 4. Hot-water pipes. 5. Steam pipes. The method most applicable in any particular case will depend upon the size of the room and the number of rooms in the building. In general, it may be stated that the smaller the space, the more simple the method. For a single room, an open fire or a stove will be sufficient; for a small house, stoves or a furnace; for a large one, one or more furnaces or hot-water or steam apparatus; and for large buildings—office buildings, for instance—"direct" or "indirect" steam." (Harrington's *Hygiene*.)

2. *Principles of ventilation*: "(1) There must be a constant stream of pure air admitted into the room. (2) The inlets and outlets should be placed as far apart as possible, so as to allow of proper diffusion throughout the room. If possible they should be placed on opposite sides of the room with natural ventilation, but on the same side with artificial ventilation. (3) The inlets for cold air must discharge some five or six feet above the level of the floor, and the outlets for vitiated air must be near the ceiling. (4) The admission of warm air can be permitted near the floor. (5) The incoming air should be itself pure and of sufficient quantity. (6) The inlets for each person in the room must equal in total area 24 square inches, and the outlets should contain the same area. (7) The incoming air must not produce a draught. (8) The ventilation of a large room is always easier than that of a small one. (9) A large room will not compensate after the first hour for a proper system of ventilation. (10) If proper inlets and outlets are constructed, all other means for the admission of air should be closed. (11) The windows of all unoccupied rooms should be opened wide so that they may be flushed with a stream of pure air." (From Evans' *Student's Hygiene*.)

3. *Water supply from*: (1) *Rain water* collected immediately as it falls as rain, dew, snow, etc. (2) *Surface water* collected in ponds, lakes, streams, etc., and in free contact with air. (3) *Ground water, or sub-soil water*, derived from the rain water of the district, but which percolates through the subsoil, and so is not directly exposed to the atmosphere. (4) *Deep or artesian water*, which is separated from the ground water by one or more impermeable layers.

4. *Diseases specially liable to be conveyed by the ingestion of milk*: Tuberculosis, typhoid fever, scarlet fever, diphtheria, tonsillitis, cholera, and gastrointestinal disorders.

The milk may come from a diseased cow; it may become contaminated by the milker, the container, the surroundings, the water used to wash the cans or to adulterate the milk; or it may become contaminated at the dealer's or purchaser's house by being left uncovered, exposed to flies, etc., or by not being kept in a cool place. The only way to prevent the transmission of disease by milk is to insist on a thorough inspection of all dairies and sources of milk supply, and to educate the public in the care of milk between the time of its purchase and its consumption. The inspection should include: the color, reaction, specific gravity, sediment, taste, odor, acidity, total quantity of solids and of water; the percentage of cream, fats, lactose, casein, and ash; the presence or absence of preservatives, coloring matter, added solids, dilution, pathogenic microorganism, dirt, or other foreign matter. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transporting the milk.

5. *Diseases transmitted by mosquitoes*: Malaria, yellow fever, dengue, and filariasis.

6. The mosquito which transmits malaria is the *Anopheles*. Its wings are usually spotted; in the resting posture, the axis of the head, proboscis and body are in the same straight line; its body is of a dark gray or brown color; the female alone bites and transmits the *Plasmodium malarix*; the larvæ float on the surface of water.

"The most efficient way of getting rid of mosquitoes is to make it impossible for them to breed. The eggs of a mosquito are laid in water, and water is absolutely necessary for the larval and pupal stages, which must be passed through before the adult mosquito is produced. Fish destroy developing mosquitoes and large sheets of water are too rough for them; so mos-

quitoes must have, for breeding, rather small collections of fresh water free from fish. Mosquitoes will soon disappear from a locality if all such collections of water, within a quarter of a mile of it, are filled up, drained, or covered with a film of coal oil so as to make it impossible for the mosquitoes to breed in them. Those who live in a malarious district should protect themselves from mosquito bites by the careful use of mosquito netting. By the simple observance of these evident indications, malaria has already been banished from several localities in which it was formerly endemic." (Marshall's *Microbiology*.)

7. *Disinfection of Rooms*: "Practical disinfection is a process which needs scientific precision and attention to details. The disinfection must be adjusted to the form and nature of infection and the infected materials and objects, each of which may need a different method of handling and disinfection. The room air needs no disinfection, for whatever germs may be found in dust of the air in a room will settle upon the surfaces whenever the room is closed and left undisturbed. The room walls if covered with paper may be efficiently disinfected by thorough rubbing with stale bread. Painted surfaces of walls and ceilings may be disinfected by washing with 3 per cent. solution of carbolic acid or a 1 to 500 solution of sublimate of mercury. Floors and other surfaces of rooms may also be conveniently scrubbed with hot water and a solution of carbolic acid or sublimate, or one of the cresols. Carpets, rugs, etc., may be efficiently disinfected by a strong solution of formalin, by gaseous disinfection with formaldehyde, or may be taken up and subjected to superheated steam under pressure. Curtains, hangings, etc., within the rooms are disinfected with formaldehyde, and may also be washed in boiling water. Wooden bedsteads may be washed with a 3 per cent. carbolic solution or a 5 per cent. formalin solution. Bedding, linen, etc., may be disinfected by steam, by formalin, and also by formaldehyde. For the successful disinfection of rooms with a gas it is necessary to close all openings, cracks and crevices, keyholes, etc., completely, and especially the crevices about windows and doors. This is done by means of cotton, or, better, by means of gummed paper strips. Raising the temperature of the room assists disinfection. The room is then closed and all openings and crevices sealed with gummed paper, and the room is left for at least twenty-four hours." (Price's *Hygiene and Public Health*.)

Sulphur and formaldehyde are the two commonest agents used to disinfect rooms.

"Municipal quarantine comprehends measures for isolating those sick with certain of the infectious diseases, such as scarlet fever, diphtheria, and smallpox, keeping others under observation, and disinfecting rooms and houses and objects contained therein which may be capable of harboring infection. It is beyond dispute that public safety requires that certain sick should be shut off from free communication with the outside world. The isolation is most complete and entails less hardship when it can be carried out at a special hospital for contagious diseases, but generally it is enforced, if at all, at the patient's home. Room and house quarantines are commonly difficult or impossible of enforcement, especially in tenement districts among the very poor, for it is among this class that danger of infection is least understood and mutual help and neighborly visiting most extensively practised, and thus the foci of infection may become increased indefinitely. In hospitals, on the other hand, where indiscriminate egress and ingress are under control and facilities for the disinfection of discharges are at hand, the danger of spread is reduced to a minimum. Especially difficult and productive of hardship is the isolation not only of the patient, but also of the other members of his family. This is commonly practised in the case of smallpox, but is unnecessary if the other members have undergone recent successful vaccination, and their clothing and other effects are disinfected and they are then separated from all possible contact and communication with the patient. But even then, they should be kept under surveillance for a time equal to the period of incubation. In times of epidemics of yellow fever in the South, house quarantine of entire families has proved to be the cause of much hardship and anything but an unqualified success. It causes great popular dissatisfaction, leads to concealment of cases, and tends, therefore, to spread rather than restrict the disease. Treatment of the sick in isolation hospitals and removal of those who have been exposed to infec-

tion to camps of detention for five full days have been found to give far better results. In some outbreaks of infectious diseases, it is necessary or advisable to conduct a house to house inspection for the discovery and isolation of unreported cases. When such a course is undertaken, the visits should be repeated at intervals equal to the period of incubation. The making of regulations for municipal quarantine and inspection is subject to no general rule, each local authority being a law unto itself. In some cities, the rules governing notification, isolation, and disinfection are exceedingly thorough and strictly enforced; in others, they are inadequate in varying degrees and enforced with laxity." (Harrington's *Hygiene*.)

8. In addition to many of the diseases which are found in temperate climates, people in the tropics are liable to: Ancylostomiasis, beriberi, cholera, black-water fever, dengue, dysentery, filariasis, leprosy, malaria, Malta fever, pellagra, plague, tick fever, trypanosomiasis, yaws.

9. To prevent disease among the troops, the surgeon should see that, as far as possible, the soldiers have pure air, pure water, and good, suitable and digestible food; that personal cleanliness is the rule; that dissipation and excesses are avoided; that protective inoculation is practised where possible; that the soldiers are instructed as to the dangers of venereal diseases; that frequent and thorough inspections are made, and that those who have any infections or communicable disease are isolated. Powers of endurance should be increased by suitable exercises; and undue fatigue and idleness must be prevented.

10. Those suffering from cerebrospinal meningitis should be quarantined till recovery; all bodily discharges, especially those from the nose and throat must be disinfected. "Carriers" must be sought for, as in diphtheria; and if found must be isolated. The public must be instructed as to the nature and seriousness of the disease.

BACTERIOLOGY AND PATHOLOGY.

1. Bacteria multiply by division or fission, and also (indirectly) by spore formation. Cocci may divide in one, two, or three directions of space. Bacilli divide transversely to their long axis. Spirilla divide transversely to their long diameter. A bacterium about to divide seems to be larger than normal, and if it is a coccus it becomes more ovoid; changes occur first in the nucleus, and the bacterium thus simply falls in two.

It has been calculated that a single bacterium could, by fission, produce two in one hour. Fortunately they seldom obtain food enough to keep up this process for any length of time.

Aerobic bacteria are such as cannot ordinarily live and grow without air or oxygen. *Anaerobic bacteria* can usually live and grow only in the absence of air or oxygen.

2. *Staining peculiarities of the tubercle bacillus.* It does not stain readily with the usual anilin dyes, but take the stain only when the staining solution is heated, or the exposure unduly prolonged. When once the stain is taken it is held tenaciously and even resists the action of acids. Hence it is said to be "acid-fast," and this property is made use of in staining sputum or other material for the tubercle bacilli, when other bacteria are counterstained after having the first stain removed by acid. It is Gram-positive.

3. The *diplococcus intracellularis meningitidis* is a non-motile, non-flagellated coccus, does not form spores, is aerobic and optionally anaerobic, pathogenic, stains by ordinary methods, is Gram-negative; it is a biscuit-shaped diplococcus somewhat resembling the gonococcus. It can be grown on blood-serum and on glycerin agar.

4. A *THROMBUS* is a blood clot formed in the blood vessels during life. The process of formation of a thrombus is called thrombosis.

Causes: Changes in the blood current; changes in the vessel wall; anything within the blood current not covered with endothelium. Generally more than one of these conditions are present.

Results: Among the consequences of thrombosis may be mentioned the formation of emboli; infarction; heart clot, and sudden death; cerebral softening; the thrombi may become organized, liquefy, soften, become calcified, putrefy, become discolored, or they may undergo revolution.

5.

	SARCOMA	CARCINOMA
1. <i>Origin.</i>	Entirely mesoblastic (connective tissue type).	Epithelial and hypoblastic. (Epithelial tissue type.)
2. <i>Stroma</i>	Intercellular. Rarely forms alveoli.	Vascular connective tissue, which surrounds and forms the walls of the alveoli; these communicate with one another, and contain masses of epithelial cells.
3. <i>Cells</i>	Granulation tissue or embryonic connective tissue cells; shape and size vary.	Epithelial cells contained within alveoli; shape and size vary.
4. <i>Intercellular substance.</i>	May be present.	Absent, or merely fluid.
5. <i>Vessels</i>	Embryonic in character. They are in direct contact with, or may be formed by, the special cells, slightly modified, of which the tumor is composed.	Well developed; entirely contained within the connective tissue stroma, and supported by the walls of the alveoli. Seldom in contact with the cells.
6. <i>Spreads.</i>	Primarily and secondarily by blood vessels, rarely by the lymphatics.	Primarily by lymphatics, except in the later stages, when it may also spread by blood vessels, in which case it spreads with very great rapidity. Secondarily by blood vessels.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

BACTERIOLOGY FOR NURSES. By HARRY W. CAREY, M.D. Published by F. A. Davis Company, Philadelphia, Pa.; 144 pages. Price, \$1.00 net.

HOSPITALS AND THE LAW. By EDWIN VALENTINE MITCHELL. Published by Rebman Company, New York; 178 pages.

A BRIEF BIBLIOGRAPHY OF WORKS ON LATIN AMERICA. By PETER H. GOLDSMITH. Published by The MacMillan Company, New York; 107 pages.

MAKERS OF MODERN MEDICINE. By JAMES J. WALSH. Published by Fordham University Press, New York. Catholic University edition, enlarged by the addition of the Life of Virchow; 441 pages. Price, \$2.00 net.

THIRTY-EIGHTH ANNUAL REPORT OF THE BOARD OF HEALTH, of the STATE OF NEW JERSEY, 1914, and REPORT OF THE BUREAU OF VITAL STATISTICS. Published by News Printing Company, State Printers, Paterson, N. J.

"SPEAKING OF OPERATIONS." By IRVIN S. COBB. Published by George H. Doran Company, New York. Illustrated by Tony Sarg; 64 pages. Price, 50 cents net.

DINNER. Tendered to Irvin S. Cobb, Waldorf-Astoria Hotel, April 25, 1915. Published by George H. Doran Company, New York; 61 pages.

ANNUAL REPORT OF THE SURGEON GENERAL OF THE PUBLIC HEALTH SERVICE OF THE UNITED STATES. For the fiscal year 1915. Published by Government Printing Office, Washington, 1915; 398 pages.

A HANDBOOK OF COLLOID-CHEMISTRY. By Dr. WOLFGANG OSTWALD. Published by P. Blakiston's Son & Co., Philadelphia, Pa.; 278 pages. Price, \$3.00 net.

NITRO BY HYPO. By EDWIN P. HAWORTH. Published by The Willows Magazine Co., Kansas City; 117 pages.

PRINCIPLES OF GENERAL PHYSIOLOGY. By W. M. BAYLISS. Published by Longmans, Green & Co., London; 850 pages.

DISCURSOS ledidos ante la REAL ACADEMIA DE MEDICINA. Del Dr. D. JUAN PESET Y ALEIXANDRE. Sevilla. Tipografia de Girones-Francos, 49; 108 pages.

LABORATORY METHODS. By B. G. R. WILLIAMS and E. G. C. WILLIAMS. Published by C. V. Mosby Company, St. Louis. Third edition. Illustrated with forty-three engravings; 214 pages. Price, \$2.50.

Miscellany.

To Combat Alcoholism.—The following resolutions adopted in Nova Scotia, the first by the Medical Society of Nova Scotia, and the second by the Conference of Medical Health Officers of Nova Scotia, are of general interest:

"That since it has been established that alcohol is not a food, in that none of its elements is incorporated into the tissues, and since the heat it produces by oxidation is over-compensated for through heat lost from the blood vessels of the skin, and since alcohol is not required to aid any physiological process, and since by its excessive use all systems of the body are injured and the moral nature so altered as to lead to crime, this meeting desires to impress the community with the benefits to be obtained by abstinence from alcohol as a beverage, and recommends its use only under medical advice. This meeting would warn the public that many patent medicines containing large amounts of alcohol are neither foods nor stimulants as advertised."

"Whereas, it has been absolutely proven that alcohol has a pernicious and injurious effect on the public health of our country, in that it lowers the resistance of the individual to disease, thereby disposing to tuberculosis and other infectious diseases; and Whereas, it is one of the chief contributing factors to poverty, misery, and crime; Therefore, we, as Health officers of the Province of Nova Scotia, place ourselves on record as opposed to its use as a beverage and strongly recommend its use only upon medical prescription."

Treatment of Chronic Tube Cases.—The Bulletin of the New York City Department of Health reports an interesting successful experiment in the treatment of patients suffering from chronic laryngeal stenosis following intubation performed in the course of laryngeal diphtheria, which affords striking evidence as to the value of fresh air in cases of affections of the respiratory tract. On July 1 eighteen of the "chronic tube cases" in the wards of the Willard Parker Hospital, together with the necessary physicians and nurses, were sent to Otisville and housed in a farm house. Their ages varied from 2 to 19 years, and they had been inmates of the hospital for from two to eight years, during all of which time none had been without a laryngeal tube for more than two months at a stretch. On July 15 four other children were sent to join the original party, and all were allowed the greatest possible freedom, as it was felt that the country air and the removal from the hospital environment might result in so great an improvement that they would be better able to withstand operative procedures in the fall. The end of the first month, to everyone's surprise, found all but four of the children doing without their tubes and nearly half of them giving no evidence of difficulty in respiration. The children remained on the farm until driven back to the Willard Parker on September 25 by the cold weather at which time eighteen were without tubes. At the time of the report thirteen of them were still without tubes and were apparently cured. As a result of this experiment the hospital authorities are planning to equip the farm house at Otisville so that it may be made an annex for the care of all chronic tube cases during at least one-half of the year.

The Horror of It.—Prof. Ludwig Schleich has spent some months at the front and also a consider-

able time in charge of a military hospital in Berlin. In his impressions now published he speaks of a strange, almost awful look in the faces of those released from the firing line. They are still willing soldiers, some of them eager to go back to the trenches, but the more highly civilized a man is, Professor Schleich says, the better educated, the deeper his feelings, the more does he bear that indelible something in his face, the sign that he has seen terrible things. Physically, these soldiers may be hard as iron, yet they are not intact. The officers nearly always develop an uncanny marble staring look, as though they had been accustomed to gaze unshudderingly at all the terrors and desolating orgies of destruction, as though they had been obliged to witness this with unblinking eyes, and finally felt that their eyes had become a mirror of the horrible. It is as though the claw of a demon had seized their faces and made their eyes sink deeper into their hollows. They are all changed, says Schleich, they have all seen the head of the Gorgon in the Region of Night, they have all been beaten by the pinion of the iron bird of Destiny.—*The Evening Post.*

Ambulance Dogs.—The 1,700 ambulance dogs now employed by the German army are said to have saved 4,000 lives. Each ambulance man possessing a dog must keep a diary of the dog's performances in order that the authorities may know which of the several breeds used proves to be the best. At Jena a special dog hospital exists, where the exhausted ambulance dogs may recuperate. Ambulance dogs are trained never to bark when they find wounded, but to return and fetch their masters.

An Effective Temperance Measure.—The "no-treating" order recently put in force in London has, the *London Times* says, had a marked effect on the habits of a considerable section of the people. The police report generally that less drink is now being sold, fewer people visit public houses, and those who do stay for a shorter time than before; and there is less drunkenness, especially among women.

The Chief Medical Examiner.—Dr. Wells, in the discussion of a paper read before the fifth mid-year meeting of the Medical Section of the American Life Convention at French Lick, Ind., said that the duty of the medical examiner is a very important one. His company had in each town what was termed a "chief examiner" and insisted on his use. They believed that they got better service in this way. If the chief is not available then an "alternate examiner" may be used. When the agent employs a doctor other than the designated chief he is required to submit in writing his reason for so doing. This presents an element of danger. The party in his home town is known. Possibly the chief examiner is the applicant's physician and consequently when taken to a strange doctor, perhaps twenty miles away, one loses the personal touch that comes from the doctor in the home town. In order then, to protect the society and its examiners as well, the referee will make inquiry of the chief examiner in the town where the examination should have been made, requesting an explanation as to his non-use, and also his opinion of the applicant, should he be able to give one. The doctor may think it presumptuous on the part of the company to write him for information when he did not make the examination, but, on the other hand, the chief examiner is protected in his right and this informs him of what the agent is doing, thus protecting his interests as well as those of the society, and the examiners are appreciating the system.

THE PERIOD OF LIFE AT WHICH INFECTION FROM TUBERCULOSIS OCCURS MOST FREQUENTLY;

HOW MAY WE DIMINISH THE FREQUENCY OF THOSE INFECTIONS AND PREVENT THEM FROM BE- COMING TUBERCULOUS DISEASES?*

By S. ADOLPHUS KNOFF, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOLOGY AT
THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOS-
PITAL; VISITING PHYSICIAN TO THE NEW YORK HEALTH
DEPARTMENT'S HOSPITAL-SANATORIUM FOR THE
CONSUMPTIVE POOR, ETC.

FOR a soldier, whether in time of peace or war, whether fighting in defense of his country and obliged to kill or fighting an insidious enemy like tuberculosis and thus seeking to save life, the first duty is to obey. Even if in his own judgment the task assigned to him seems impossible, if his superior officer commands it he must do the best he can.

These were about the thoughts that came to my mind when my superior officer, Dr. W. S. Rankin, the chairman of the program committee, assigned to me the above topic to present before the Public Health Officials' Section at this meeting. I asked myself, who knows anything about the period of life at which infection from tuberculosis occurs most frequently? I was sure I did not. My own statistics tell only of the occasionally recalled exposure to infection during adult life and of the cases of tuberculosis of either parent where there was a likelihood that infection had taken place some time during infancy or childhood, or even later, but at what exact age I had no way of knowing. In fact, I always thought that while it is possible to get statistical data of the period at which the tuberculous disease manifests itself, it is utterly impossible to determine the exact period of infection. But I was not going to be discouraged because of my own ignorance, and the fact that I did not know the period of life at which infection from tuberculosis occurs most frequently did not at all mean that others might not know a good deal about it. So in order to carry out the program, I determined to find out what information I could get on this subject.

I wrote forty letters to well known specialists on tuberculosis and to internists who see a good deal of tuberculosis in their consultation practice,

*A revised and enlarged article which was originally read by invitation before the American Public Health Association at its 43rd Annual Meeting in Rochester, N. Y., September 8, 1915. Since the date of the reading of the address, many answers to letters of inquiries have come in and important events have transpired which made a revision and some changes necessary.

and twenty letters to well known authorities on diseases of children.

I asked for the percentage of children infected with tuberculosis in general, at what age in particular, and what organs were most frequently involved. I then asked for the method of invasion and how often the infection could have been considered prenatal. I tried to ascertain at what period of life an infection, contracted in infancy or childhood, had the greatest likelihood to become active, and at what period of life in general tuberculosis had been found most frequently in the adolescents and the adults. Lastly, I asked my correspondents, in case no statistics were available, to favor me with their general impressions on the subject.

Many of my correspondents did not fail to impress upon me the difficulty of the task I had undertaken; some wrote encouragingly and some discouragingly, but all agreed on the great vital importance of such a study. Following are quotations from a few of the letters I received:

From our beloved Dr. E. L. Trudeau, the great scientist and scholar, friend and beloved physician, whose recent passing away deprived us of the greatest American authority on tuberculosis, but who, let us hope, has left with us his spirit, his enthusiasm, his devotion to the cause and inspiration to go on and on with the work, I received the following kindly note: "You must excuse me from answering the questions you are asking the rest of the profession. To be accurate it would involve an amount of work which I really don't think I can give to it. I hope the result of your inquiries will throw some light on this very obscure question."

Dr. Lawrason Brown of Saranac Lake said: "Really an inquiry such as your question would indicate would settle the whole matter, but it seems to me almost impossible to determine the answer to question 6 (concerning mode of invasion). This would be largely guesswork, but if it could be based on scientific research would settle many vexed questions. I might say that I feel that the whole subject of etiology should be gone over again and some of us here are planning to do a little work in the matter."

Prof. S. Solis-Cohen of Philadelphia said: "I shall be much interested in the result of your studies, and especially in your conclusions from your own statistics, which to me would be of vastly more importance than the guesses of all the rest of us put together." (I wish the good doctor were half right in this assertion.)

Prof. Theodore C. Janeway, of Johns Hopkins University, Baltimore, wrote me from his summer home: "The problem you have taken up seems to me one of the most fundamental for our understanding of the mode of infection in tuberculosis and for the

selection of effective measures of prevention. Exact statistics from a large number of sources on each of the points you raise will be of great help towards its solution. I wish I might contribute some, but I am entirely out of reach of my data, which are in Baltimore. I am most anxious for light on this problem and shall await the results of your study with great interest."

Prof. William P. Lucas of San Francisco, makes the following significant statement: "I should be very glad to see your report lead to some immediate and definite attempt to really take up the subject from a statistical and scientific standpoint on a large scale throughout this country including all the children's hospitals in at least the university centers."

Dr. David R. Lyman of the Gaylord Farm Sanatorium wrote me: "I greatly regret that it is impossible for me to find time to go through my records for the data for which you ask. I recognize the great importance of the question and the need for its presentation and discussion."

Prof. John L. Morse of Boston, writes: "It seems to me that in general a great many statements are made regarding tuberculosis in infancy and childhood on an insufficient basis. It seems to me, moreover, that a great deal of the discussion which is now going on about tuberculosis in childhood is in relation to entirely unimportant points and that there is danger of overlooking or neglecting the few important points."

Dr. Joseph E. Winters, professor of Clinical Medicine, New York, writes: "My experience at Cornell and elsewhere convinces me that the diagnosis of tuberculosis in children is at present too hastily made and on insufficient evidence. Tuberculosis in childhood is not a latent disease as in adults. With the exception of glandular tuberculosis, it is an active and rapidly progressive disease. Its symptoms and signs are distinct, clear, and unmistakable. Would that I had the time to devote to the subject which it merits."

My good friend, Dr. Charles L. Minor of Asheville, N. C., does not think a lifetime enough to go over his statistics, and this is what he says concerning them: "I have a vast amount of carefully kept histories, but I have no time to get up statistics out of them, and I expect I will be dead before that opportunity offers. In fact, I think we could have a very nice time in Heaven going over and catching up with the work we had begun on earth." May Dr. Minor be spared a long time to continue his work on this earthly sphere, but when the time does come for him to pass to his heavenly abode and reward, I hope he may find more pleasant work to do in the other world, unless, of course, he should find working on tuberculosis statistics the most congenial heavenly occupation.

I must quote from another letter received a few months ago, not amusing and cheerful like the foregoing, but, on the contrary, deeply sad and depressing, coming from the war zone where they are trying to do the very reverse of that for which we are assembled here. While we are bending all our energies to save life, prevent untimely death and to further human happiness and peace, in Europe at this very moment they are sacrificing their best and most virile youths, killing and maiming thousands and sowing the seed of hatred and enmity among the nations. This must have been the thought of the Regius Professor of Oxford, Sir William Osler, when he wrote to me.

This great man, though far removed from us, still takes the keenest interest in the work of his American pupils and friends. After giving me most valuable bibliographical indications, he says: "I am afraid I would not have time to look over my material and answer those questions intelligently. We are all working hard here. It is an awful business. One of the worst features is that it will dig an intellectual gulf between Germany and this country for generations. Let me have the results of your studies." May the great doctor's prophesy not come true and an early and lasting peace again unite the nations.

Prof. A. Jacobi, that grand old man, 85 years young, sent me from his summer home a five-page letter, closely written in his own hand, giving me a wealth of information. At the end of this remarkable document full of bibliographical references and narrations from his own vast experience, he modestly says: "I am sorry I cannot contribute anything to your work, being in the country and having nothing in this desert that will add to your riches." Of course the good doctor refers to the riches of information I was supposed to have gathered from other sources since I have confessed to having none of my own.

Many other letters began with the usual regret not to be able to answer all my questions or some of them, or even any at all, because of lack of statistics, but from what follows you will see that a goodly number of my correspondents have most kindly aided me by letting me have whatever statistics they had or giving me the general impressions resulting from their vast experience. Adding to this whatever important enlightenment I could find by the perusal of the more recent current literature, I believe I have after all been able to come to some conclusions, and from them we may perhaps be able to outline some effective measures to diminish the sources of infection and to prevent the tuberculous infection from becoming tuberculous disease.

The answers to my first question, concerning the frequency of tuberculosis in childhood, would give an average of about 36 per cent.

Prof. Norman Bridge of Los Angeles gave it as	22 per cent.
Prof. S. Schs Cohen, Philadelphia, gave it as	10 per cent.
Dr. Alfred F. Hess, New York, gave it as	38 per cent.
Prof. Godfrey R. Pisek, New York, gave it as	65 per cent.
Dr. Bertram H. Waters, New York, gave it as	26 per cent.
Hamburger and Monti, in Amer. Jour. of Dis. of Child., Vol. 9, No. 6, June, 1915, gave it as	59 per cent.
Veeder and Johnston, in same issue, gave it as	34 per cent.

From the interesting opinions given in answer to this inquiry I desire to quote the following:

Prof. Vincent Y. Bowditch of Boston thinks latent tuberculosis is more frequent in children than has hitherto been supposed, only to become active in young or adult life.

Prof. Edward O. Otis of Boston writes: "I believe a large number of children have a tuberculous infection but comparatively few develop active clinical pulmonary tuberculosis before adolescence. Such I should say had been my experience."

Prof. William P. Lucas of San Francisco, feels strongly that it is time to differentiate between infection and disease in children. He believes that most city children become infected and in most cases produce definite immunity.

Dr. Alfred Meyer, New York, thinks the percentage higher than usually supposed in febrile cases without superficial evidence, such as lymph-node and joint lesions, and that these cases are wrongly regarded as typhoids (even three or four attacks).

Prof. John L. Morse, Boston, says tuberculous infection is of course very common, while tuberculous disease is relatively rare.

Newsholme, in *Lancet*, June 12, 1915, in the section referring to inaccurate diagnosis in children, quotes striking figures from Coates and Landouzy on the question of the prevalence of tuberculosis in children and also in relation to deaths. He states that "in children the term bronchopneumonia not infrequently conceals acute tuberculosis, especially when the "bronchopneumonia" occurs after imperfect recovery from such diseases as whooping cough and measles."

Concerning the various ages at which infection has most likely occurred, I received the following replies:

Dr. Alfred F. Hess, New York:

Under 1 year	5 per cent
1 to 2 years	53 per cent
2 to 5 years	75 per cent

Prof. John L. Morse, Boston. Infection and disease increase steadily with age.

Prof. Godfrey R. Pisek, New York:

1st year	14 per cent.
2nd year	50 per cent.
3rd year	65 per cent.
5th year	60 per cent.
7th-14th year	70 per cent.

Prof. Geo. M. Tuttle, St. Louis: Most frequent under 5 years of age.

Prof. J. A. Miller and Dr. I. O. Woodruff (*Jour. of A. M. A.*, March 27, 1909): In children of tuberculous parents who live in close association with them, between 2 and 15 years, 51 per cent.

Prof. Hamburger of Vienna, in "Handbuch der Tub.", Bd. V, 1915, gives the following table:

1st year	1 per cent.
2nd year	9 per cent.
3 to 4 years	27 per cent.
5 to 6 years	51 per cent.
7 to 10 years	71 per cent.
11 to 14 years	94 per cent.

My own statistics reveal the following: Infection occurred apparently in children.

1 to 5 years	9 per cent.
5 to 10 years	34 per cent.
11 to 15 years	12 per cent.

Prof. Theodore Le Boutillier's remarks in answer to this question are likewise of intense interest. He says that he found that infection occurs with comparative infrequency during early infancy when the child has been removed from the infected surroundings. He never found it to occur under these conditions. Where, however, the child remains in the infected surroundings, he thinks that, as a rule, these infants become actively tuberculous within the first year of life. It occurs most frequently during the second five years of life and then at puberty.

To the question which of the organs were most frequently involved, nearly all my correspondents united in the opinion that in children the lungs and lymph nodules were primarily and most frequently involved; secondly, bones; thirdly, intestines; fourthly, meninges.

I will quote from the comment I received on this question as follows:

Dr. E. R. Baldwin of Saranac Lake referred me to his article in Osler's System of Modern Medicine, last edition, in which he says: "In the majority a previous focus must be regarded as essential, although infection through the tonsils or by way of the cribriform plate of the ethmoid may be possible. The most frequent lesion is in the lungs (50 per cent.), glandular tuberculosis probably comes next in frequency, and then joint, bone, genito-urinary, and pleural lesions."

Prof. Theo. Le Boutillier of Philadelphia thinks that the younger the child the more likely it is to be meningitis, next in frequency miliary tuberculosis; in older children, pulmonary, glandular and bone.

Prof. William P. Lucas says that acute tuberculosis, in his experience, is nearly always found in

infancy and rarely during childhood unless the infection is very virulent or quantitatively large. After 5 years of age the number of acute cases even of tuberculous meningitis or miliary tuberculosis diminish very rapidly. He has no absolute percentage from his own experience but thinks that practically all the infections are glandular, either peribronchial, peritoneal, or cervical, and that the other forms of tuberculosis, bone, etc., are secondary to the glandular involvement.

Dr. Alfred Meyer has always been surprised at the comparative rarity of acute miliary and of meningitis considering the very favorable conditions for dissemination.

Prof. John L. Morse supposes that tuberculous meningitis and miliary tuberculosis are always secondary to some previous infection.

As to the method of invasion, Prof. John Howland of Baltimore gave 95 per cent. through close personal contact with tuberculous individuals. Prof. Godfrey R. Pisek of New York, 75 per cent. Professors Hermann M. Biggs and Henry D. Chapin of New York, William P. Lucas of San Francisco, and George M. Tuttle of St. Louis, concur in the opinion of Dr. Howland.

In our Health Department's clinics, Dr. Bertram H. Waters traced the majority of infection to the respiratory tract. My own statistics made me come to the same conclusion.

Somewhat divergent is the view expressed by Prof. Frank Billings of Chicago, who says it seems to him that the most common source of the infection in the child and adolescent is through the digestive apparatus, either from infected milk or other food substances or quite as frequently from actual contact with tuberculous adults and the contamination of hands, lips, etc., and with tubercle bacilli which gain entrance through the mucosa of the throat. He often wondered if this method of contact infection is not frequently present even in the adult rather than infection through infected air as is the commonly accepted mode. In other words, the last named mode of infection it seems to him is a very common one in both children and adults.

Prof. L. Emmett Holt, on the other hand, says that it has always been his belief that the dangers from tuberculous milk have been greatly exaggerated, certainly with infants and young children.

Prof. John L. Morse says that he has seen a considerable number of cases in which children with tuberculosis had taken the milk from tuberculous cows. He does not know, however, whether their infection was from the tuberculous milk or whether it was acquired in some other way.

As appertaining to this question we must add the following: Prof. William Charles White of Pittsburgh writes that in no way could he see that it is possible for us to trace the origin of infection from without, although, in most of our general tuberculous cases, on which we have had autopsies, it is possible to trace infection from some glandular source of infection within the body.

Prof. Godfrey R. Pisek says, infections with human bacilli, in all probability are the latent types; the bovine type of infection does not seem to remain latent and to develop in later life; perhaps this type even confers a certain immunity.

Dr. Beverley Robinson of New York says: "The pulmonary organs are those most frequently involved, as I believe, and that is also the impression of very many general practitioners."

My question concerning the frequency of pre-

natal infection received the least number of responses. Prof. Norman Bridge thought he had seen two cases; Prof. John Howland also two cases; Prof. A. Jacobi reported one case. Myself I believe to have observed two distinct cases of prenatal infection. Professor Pisek believes that only fifteen authentic cases have been reported. And yet, it seems to me this rarity is perhaps only apparent and the reason for it is to be found in the fact that autopsies in children are not made nearly as frequently as in adults. There have been a sufficient number of cases on record, however, to make it necessary to consider this direct bacillary transmission from the mother as one of the means of tuberculous infection, particularly when the mother has been acutely ill at the time of conception or during pregnancy.

This prenatal infection may also explain the occurrence of tuberculosis in early infancy, that is to say before the first year. Gärtner, of Jena, ("Ueber die Erbllichkeit der Tuberkulose," Zeitschr. f. Hygiene u. Infektionskrankheiten, Bd. XIII), who made very extensive animal experiments in the endeavor to remove all doubts about this much disputed question, comes to the conclusion that the experiments with rabbits and guinea pigs disprove the possibility of the transmission of the tubercle bacillus from the father to the fetus. When bacilli are very numerous in the semen, the mother becomes infected but never the offspring. On the other hand, the clinical reports and his own animal experiments have convinced him that tubercle bacilli are frequently transmitted from the mother to the child during the latter's prenatal existence.

Some time ago I had the honor of a conversation with Prof. William H. Welch of Johns Hopkins Medical School, on the subject and he, too, was of the opinion that a direct bacillary transmission, that is to say, prenatal infection, takes place much more frequently than is generally believed.

Prof. S. Solis Cohen says it is difficult to distinguish between prenatal infection, hereditary tendency, and infection early in life. He does not see a sufficient number of very young infants to be able to exclude the latter method in any instance.

Prof. A. Jacobi says that while direct heredity is rare, hereditary predisposition to tuberculosis is quite frequent, and is transmitted even by such parents as appear to be in fair health. It is evident that the newly-born cannot be safe with its consumptive mother.

As to the certainty that predisposition is frequently inherited from a tuberculous mother or a tuberculous father, an anemic parent, or parents of feeble health or generally below par, there is, of course, not the slightest doubt. Any inherited weak system which might be more properly called a physiological poverty, renders the child naturally more susceptible and less resistant to the invasion of tuberculosis or other infectious diseases. When the mother is the tuberculous parent, this predisposition is all the more likely to be inherited because of the impregnation of the cells of the fetus by the toxins of the tubercle bacilli, even if the latter have not been found in sufficient numbers in the cells to demonstrate direct bacillary transmission.

To the question at what period of life a tuberculous infection, contracted in infancy or childhood, was most likely to become active, I received the following answers:

Dr. W. Jarvis Barlow, Los Angeles, at	15 years
Prof. Hermann M. Biggs, New York, between	6 and 25 years
Prof. S. G. Bonney, Denver, between	18 and 25 years
Prof. Vincent Y. Bowditch, Boston, at	15 years
Prof. Norman Bridge, Los Angeles, between	15 and 18 years
Dr. E. S. Bullock, Silver City, N. Mex., between	18 and 25 years
Prof. S. Solis Cohen, Philadelphia, between	18 and 50 years
Prof. Theo. Le Boutillier, Philadelphia, at	15 years
Prof. Wm. P. Lucas, San Francisco, at	15 years
Dr. Alfred Meyer, New York, at	10 years
Dr. Charles L. Minor, Asheville, before	16 years
Prof. Wm. P. Northrup, New York, between	3 and 12 years
Dr. Bertram H. Waters, New York, most frequently under	2 years
next in frequency between	15 and 20 years
In my own experience early infection became active between	10 and 30 years

The remarks on this question are significant and I will quote the following:

Dr. Alfred F. Hess of New York does not believe that the age is such an important factor as regards making an inactive process active, as is the general condition of the individual. Independent of age, if a person has measles, marked anemia, or malnutrition from whatever cause, there is liability of the lighting up of the tuberculous focus.

Dr. G. W. Holden of Denver thinks a latent infection will not develop until such a time as the natural resistance has been broken down and vitality lowered, due to overwork or overplay, or a combination of both.

Prof. L. Emmet Holt, New York, thinks that age seems to have much less influence on this point than other conditions, such as season of year—winter and spring—and the development of intercurrent diseases, such as measles, whooping cough, influenza, and bronchitis.

Dr. David R. Lyman of Wallingford, Conn., says that his own general impressions based chiefly upon the histories of his cases is that where an intelligent history is obtainable a very large percentage of our adult cases can be traced back to early youth or childhood, and that our future work must be devoted mainly to the prevention of tuberculosis in childhood.

Prof. William Charles White thinks that there is no period in life when tuberculosis may not be contracted.

Prof. Godfrey R. Pisek thinks the period of life in which latent tuberculosis is most likely to become active begins about the fifth year; this includes no observations after the fourteenth year of life.

To my last question, what was the age at which tuberculosis was found most frequently in the adolescent and the adult, I received the following answers:

Dr. W. Jarvis Barlow, Los Angeles, gave the age at	20 to 29 years
Prof. Hermann M. Biggs, New York, gave the age at	16 to 25 years
Prof. Frank Billings, Chicago, gave the age at	15 to 25 years
Prof. Vincent Y. Bowditch, Boston, gave the age at	20 to 40 years
Dr. E. S. Bullock, Silver City, N. M., gave the age at	18 to 25 years
Dr. G. W. Holden, Denver, gave the age at	20 to 25 years
Prof. S. Solis Cohen, Philadelphia, gave the age at	18 to 22 years
Dr. Alfred Meyer, New York, gave the age at	15 to 40 years
Dr. Chas. L. Minor, Asheville, gave the age at	20 to 40 years
Prof. Edw. O. Otis, Boston, gave the age at	18 to 35 years
Dr. Bertram H. Waters, New York, gave the age at	25 to 40 years
Prof. Wm. Chas. White, Pittsburgh, gave the age at	20 to 40 years
In my own experience I found tuberculosis to be in evidence most frequently between	15 to 40 years

Of 1,000 private cases of adults of which I kept careful records, only 14.5 per cent. recalled an evident exposure to infection outside of their family circle during their adult existence as a possible cause of their disease. On the other hand, 33 per cent. stated that either father, mother, brother, or sister had died of tuberculosis or had been ill with the disease. In these cases we have reason to believe that infection occurred most likely during infancy or childhood.

The general impressions which were kindly given me by my correspondents concerning my inquiry as to when a tuberculous infection became a tubercu-

lous disease, or when the disease was first noticed in the adolescent or the adult, are to my mind fully as valuable as the statistical data.

Dr. Herbert M. King, physician in chief of one of our largest sanatoria where the vast majority of patients come from the well-to-do classes, writes as follows: "Speaking very generally, I think I share a widespread impression, amounting to almost conviction, that most of the cases of tuberculosis developing in adult life may be traced to infection received before adolescence."

Dr. Lawrence F. Flick of Philadelphia says: "From my experience in tuberculosis and from the studies I have made of the subject, I am led to believe that ordinary tuberculosis is implanted in early life and either remains dormant or grows very slowly until adult life is reached. My histories of cases taken as a whole would indicate that ordinary tuberculosis has existed for many years when a case comes under observation for the first time. The implantation undoubtedly most frequently takes place in the home, through prolonged intimate contact with an open ulcerative case of tuberculosis in the intimacy of family life."

Prof. William C. Hollopeter of Philadelphia writes: "I am a great believer in the early implantation of tuberculosis in children and believe that all children have it with very rare exceptions; the adult form is simply a recrudescence, or an expression due to lowered resistance."

Prof. John Howland of Johns Hopkins says: "We have had, in the dispensary and hospital, since I have been in Baltimore, 8,293 patients. Of these, 469 had tuberculosis recognizable in some form or other and we have not made the diagnosis of tuberculosis unless, in addition to the symptoms, tuberculin tests showed the presence of the disease. I have not included in this those patients that, without other evidences of tuberculosis, gave positive von Pirquet reactions."

Dr. Martin F. Sloan, superintendent of the Maryland State Hospital for Consumptives, writes: "I do not remember having seen one adult with a so-called acute invasion in whom a chronic lesion was not demonstrable in one of the apices. My limited experience leads me to believe that practically all cases of pulmonary tuberculosis in the adult are of endogenous origin. A carefully obtained history from an observing patient most frequently reveals one of a number of several manifestations of tubercle bacilli infection in early life, viz., nasal catarrh or middle ear trouble, tonsils and adenoids, 'white swelling,' malnutrition, 'winter colds,' enlarged cervical glands at puberty, amenorrhea, or irregular menstruation, nervousness, and poor development; and later, pleurisy, chronic bronchitis, 'typhoid pneumonia.' In other words, we find stepping stones, if you will, connecting an infection in early childhood with the pronounced case of consumption in adult life. This leads me to say, parenthetically, that I consider the critical periods of a woman's life, in so far as tuberculosis is concerned, are puberty, puerperium, and the climacteric; of a male's, puberty and about 30 to 35 years."

"Again, a careful history nearly always shows that at least one brother or sister, or maybe more, has had suspicious symptoms. I know several families that have been exterminated by consumption, though the members had been separated since childhood, all of which would seem to indicate an infection through a common carrier in early life, very likely a parent, nurse, or housemaid."

"On the other hand, I know of no employee about the sanatorium who has become a victim of the disease. After seven years' exposure I myself show no signs or symptoms of the disease. I must confess I am somewhat dubious of the frequency of adult infection, except in cases of the closest contact, such as is to be found in marital life."

Dr. Charles L. Minor of Asheville writes: "In my own experience I have found in the adolescent the largest number of cases of tuberculosis appearing at about sixteen. In the adult the large majority have been between twenty and forty."

Prof. William S. Thayer of Baltimore wrote: "As time has gone on I have been very much impressed in a purely general way with the feeling that most tuberculosis was acquired in childhood, but, alas, when it comes to a question of proof or even of strong evidence to support my feelings, I have it not. I have a very general feeling that glandular tuberculosis is especially common in childhood and I would be inclined to believe that most pulmonary tuberculosis was rather largely an autogenous infection from such early glandular foci, but as I have said, I cannot feel that I am justified in expressing more than an impression with regard to the question. I shall be much interested to see your final conclusions."

Prof. John L. Morse of Harvard Medical School writes: "Both tuberculosis infection and tuberculosis disease are far more common among the poorer classes than among the well-to-do."

This statement that tuberculosis infection as well as tuberculosis disease is the lot of the child of the poor is borne out by the statistics furnished me, particularly those of Dr. Alfred F. Hess, who writes: "Among the children at the Infant Asylum who may be considered about the average of those living in the tenements, we have found that three-fourths of those under the age of 5 years give a positive von Pirquet test."

In these children 75 per cent. means not infection but tuberculous disease, more or less active, for below the age of 5 the infection has rarely had a chance to become latent and the slightest additional pathological process, such as measles or anemia, or simply malnutrition, is sufficient to produce a general and often fatal tuberculosis.

To make a brief summary of results from this little study, we would have to say that tuberculous disease in childhood, compared with tuberculous infection, is relatively rare (36 per cent.); that, on the other hand, tuberculous infection is exceedingly frequent, generally speaking, and according to exact statistics as well as general impressions given by men of vast experience, the majority of the cases in the adult had their origin in an infection during infancy or childhood.

The frequency of infection increases with the age of the child, and of course is also affected by the environments the child comes from.

Under 1 year, the lowest percentage is 1 per cent.; the highest is 9 per cent.
From 1st to 3rd year, the lowest percentage is 9 per cent.; the highest is 50 per cent.
From 3rd to 5th year, the lowest percentage is 27 per cent.; the highest is 75 per cent.
From 6th to 10th years, the lowest percentage is 34 per cent.; the highest is 75 per cent.
From 11th to 15th years, the lowest percentage is (private) 12 per cent. the highest is (hospital case) 94 per cent.

As to what organs are primarily most frequently involved, statistics and impressions both give lungs and lymph nodules. Prenatal infection, while considered rare, is perhaps much more frequent than statistics show.

The age at which a tuberculous infection, con-

tracted in infancy or childhood, becomes active is, according to the majority of my correspondents, at or shortly after 15 years; next between 18 and 30 years.

The ages at which tuberculosis was diagnosed and apparently contracted most frequently in later life were given as between 20 and 35 years.

Nearly all the authorities consulted unite in the opinion that in order to combat tuberculosis successfully in the young and the old, we must diminish the sources of infection in childhood.

And now, in conclusion, let me rapidly enumerate the measures which I hope and believe may tend to diminish this frequency of infection and, when it does occur, prevent the disease from developing.

1. We must seek to amend the federal and State laws which make it a criminal offense for a duly licensed physician in good standing to give advice concerning the means of preventing conception. We must be allowed fearlessly and openly to instruct tuberculous parents how not to procreate a tuberculous race.

2. All cases of open tuberculosis, particularly the pulmonary and laryngeal types, should be required by law to be reported to the health authorities who in turn should be authorized to send the patient direct or through the attending physician carefully worked out instructions to prevent infecting others.

3. Cases which cannot be properly taken care of in the home, or when it is evident that they constitute centers of infection, should be transferred to sanatoria, special hospitals, or at least to special wards in general hospitals. Every community should have sufficient facilities to take care of such cases. The Board of Health of every community should have police power in order to be able to isolate all cases which wilfully disseminate bacilli by indiscriminate expectoration or by other unclean habits, thereby exposing other members of the family, particularly children, to contracting the disease.

4. For the pregnant tuberculous woman there should be a maternity sanatorium or a special ward in existing maternities where prolonged antituberculous treatment can be effectually carried out and where mothers can receive such instructions as will guard their offspring from postnatal infection.

5. Where there is the slightest suspicion of tuberculous infection of the infant by the mother, the child should have a healthy wet-nurse or should be bottle-fed. The preparation of the milk and bottles, tasting the milk to judge of its sweetness and temperature, etc., should be attended to not by a tuberculous mother, but by an intelligent and conscientious healthy person, unless the mother is scrupulously clean and knows how to take every proper precaution against infection. For infants whose mothers for one reason or another are unable or not intelligent enough to care properly for their tuberculous offspring, there should be established special preventoria. The need of such institutions has been very ably set forth in a recent contribution by Dr. Alfred F. Hess of New York, entitled "The Neglect to Provide for the Infant in the Antituberculosis Program."*

6. Enterprises similar to the one inaugurated by my regretted teacher, the late Professor Grancher of Paris, for the purpose of providing medically supervised country homes for poor tuberculous mothers and their children until they can safely re-

turn to city environments, should be helped by private philanthropy, or better yet, by the aid of the municipality.

7. All children under five years of age, be they of poor or rich parentage, should be subjected annually, or even semi-annually, to the von Pirquet test, and all who react positively and have symptoms and physical signs in addition should be placed under proper treatment at home, in preventoria, or sanatoria.

8. All children between 5 and 15 years of age, particularly those attending public schools, should be subjected to a careful physical examination on entering as a pupil and an annual re-examination thereafter, always accompanied by a von Pirquet test. Those reacting positively and showing physical signs, those evidently strongly predisposed to tuberculosis, anemic, highly nervous, or afflicted with cardiac disease, should, according to their condition, be placed in open-air classes, open-air schools, preventoria, seaside or inland sanatoria. This will probably mean that open-air schools must become the rule and the indoor class the exception, which, indeed, would be a great blessing. It goes without saying that all physical defects, such as adenoids, enlarged tonsils, deviated septi, must be removed so that the child's upper respiratory tract may be as nearly perfect as possible. Defective hearing and eyesight, as well as bad teeth, must, of course, also receive proper attention.

9. Open-air instruction should be practiced whenever feasible. Singing, recitation, geology, botany, etc., should be taught out-of-doors. Calisthenics, breathing exercises, and swimming lessons should constitute a part of the curriculum of every public and private school. No public school should be without its swimming pool. A drill in swimming, so as to know how to save one's own or perhaps other lives, should be as essential as fire drills in public schools. Wherever shower baths and swimming tanks (the former to be used prior to entering the latter) form a part of the public school equipment, pedagogues have observed a better morale and better work done by the pupils. The curriculum of our schools should be arranged so that the mental and intellectual training is not carried to the extent of becoming detrimental to the physical development and well-being of the children.

10. The school authorities should have the right to investigate the home of any child attending public school when the teacher or school physician thinks that underfeeding, bad sanitary home environments, or child labor at home are responsible for a poor physical condition of the pupil which might develop into tuberculosis.

11. Child labor in factories, mines, canneries, stores, workshops, in the street, or at home must be done away with if we wish to raise a non-tuberculous race. Up to the age of 14 every boy and girl should have the right and privilege to play and not be forced to work. When arriving at the age of puberty, the boy or girl should be in the best possible physical condition or else there is a great likelihood that a latent tuberculosis or inherited predisposition will develop into tuberculous disease. Playgrounds and parks should be in abundance in every civilized community. The roofs of schools and tenements should be converted into roof gardens when the ground is scarce and expensive, as for example in New York City.

12. There should be an obligatory examination for tuberculosis and other serious diseases of every

**Jour. Amer. Med. Ass'n.*, Dec. 19, 1914.

boy or girl prior to entering college, the store, the workshop, the office, mine, factory, or any occupation for his or her career in life. The physical and mental test at such a time should be used as a guide in the choice of trade or profession.

13. There should be periodical examinations for tuberculosis of all employees in whatever sphere of activity—in office, factory, workshop, hotels, households, schools, municipal or federal departments, etc.

14. For those weeded out as tuberculous or afflicted with other diseases which incapacitate them for their usual work under ordinary conditions, there should be agricultural and industrial colonies where these semi-invalids will have nevertheless an opportunity to earn a livelihood. There also the graduates from sanatoria should be sent for an opportunity to regain strength and vigor, to make their cure more lasting, and above all to learn again to earn their living.

15. There should be State insurance or obligatory private insurance against accident, old age, and diseases, including tuberculosis, for all earning less than \$1,000 per annum, so that those fearing temporary or total loss of earning capacity will not be afraid to seek proper treatment in tuberculosis institutions.

16. Although the investigations, the replies from eminent authorities, and the literature consulted seem to show that the bovine type of the bacillus of tuberculosis at a maximum estimation is not responsible for more than 10 per cent. of tuberculosis in childhood, we must not allow ourselves to lessen our efforts to combat the disease in animals. We should not have individual and widely differing State laws, but instead uniform bovine laws enforced by federal authorities in all States of the Union alike. Only thus will we be able to combat the source of infection for human beings which comes from the bovine race.

17. With all this there must be a continued propaganda for the education of the masses concerning the prevention of tuberculosis, alcoholism, and other social diseases; for the improvement of housing conditions, including the supervision and better sanitation of city and country schools, of lodging houses, boarding houses, factories, workshops, stores, offices, asylums, prisons, and reformatories; for the prevention of injurious overwork; for healthful recreation of the masses in city and country; for the return to the soil from our overcrowded cities; and above all, for a living wage for all who labor honestly and efficiently and a rational and speedy solution of the problem of unemployment.

I grant that this is an elaborate and extensive program, but if you take into consideration the financial sacrifices this nation is annually making to combat tuberculosis, you will perhaps see the justification of it. In spite of all our efforts, we are still losing about 200,000 people annually from tuberculosis in the United States, of which, I venture to say, 50,000 are children. Estimating the average duration of life of these 50,000 children at about seven and one-half years, and figuring the cost to parents and the community for each life as only \$200 per annum, the financial loss thus represented is \$75,000,000. These children have died before they have been able to give any return to their parents and the community. What a useless sacrifice of life and of money! How much needless sorrow and heartaches caused to parents! Besides all this, many a tuberculous mother has had her

life shortened because she bore one of these children.

According to the report of the Commissioner of Education, there are at this time about 20,000,000 children attending public schools in the United States. Placing the proportion of tuberculosis among them as low as only 3 per cent. would make 600,000 children afflicted with tuberculosis who are at this time in urgent need of open-air instruction or sanatorium treatment. According to available statistics, we can at present provide instruction in open-air classes for about 2,000 tuberculous children. The anemic, the nervous, and the children suffering from cardiac diseases, who are in equally great need of outdoor instruction, are not included in the 3 per cent.

The 150,000 adults who die annually of tuberculosis have on the average been ill and incapacitated for work for at least two years, and figuring their cost to the commonwealth (either to municipality or individual family) at only \$1,000 per year, would mean \$300,000,000 uselessly spent in caring for people afflicted with a disease that might have been prevented or cured. Of these 150,000 adults, a large number have been married and in many instances leave either widow or orphans depending upon public support. The annual maintenance of these widows and orphans must, of course, also run into the millions. We have thus an annual expenditure of well-nigh \$400,000,000. Yet this by no means represents all the actual loss to the community from tuberculosis. Our social economists tell us that between the ages of 16 and 45 every adult life with an average earning capacity represents an asset of \$5,000 to the community. Now, as two-thirds of all deaths from tuberculosis in adults occur between these ages, we have an additional loss of \$500,000,000. Thus, the actual direct and indirect loss caused by deaths from tuberculosis in the United States amounts annually to something like \$900,000,000, and this amount we spend on a preventable and curable disease!

We must also bear in mind the fact that we have at least eight times 150,000 tuberculous adults, for it is well known that for every individual who dies of tuberculosis there are eight living with the disease, still up and about, and the majority of them with an opportunity of spreading infection. Besides these, there are 400,000 to 600,000 tuberculous children. By reason of lack of open-air schools, preventoria, sanatoria, special hospitals, and horticultural, agricultural, and industrial colonies, the vast majority of nearly 2,000,000 tuberculous individuals continue the chain of infection and keep up our fearful morbidity and mortality at an expense of \$900,000,000 per annum.

To carry out the program I suggest will not cost us \$900,000,000 a year. If at first it should even approach this vast sum, within a very few years the expenditure as well as the morbidity and mortality from tuberculosis will be reduced to a minimum.

This little study, inadequate and doubtlessly defective in some respects, has nevertheless convinced me that there never will be a solution of the tuberculosis problem if we do not attack tuberculosis in infancy and childhood. This must be done first by diminishing the sources of infection; secondly, by curing the curable.

While I am willing to grant that an early and benign infection may be an immunizing factor, we know that it is neither universal, permanent, nor complete, hence we must spare no efforts to dimin-

ish all sources of infection. It is the safer way. The measures outlined will prevent a benign infection from becoming disease and render the young child or adolescent more immune to future infections by increasing the natural resistance. The most expedient way to carry out the suggested program would of course be by a Federal Commission on Tuberculosis which I have ventured to suggest a number of times, but the need of which has been set forth very recently and most convincingly by Lee K. Frankel, Ph.D., sixth vice-president of the Metropolitan Life Insurance Company, in a paper entitled "A Plea for a Federal Commission on Tuberculosis." This paper was read before the Mississippi Valley Conference on Tuberculosis, September 30, 1915. This conference as well as the South Atlantic, New England, and North Atlantic Tuberculosis Conferences have unanimously adopted resolutions endorsing such a commission.

The child of to-day is the man of to-morrow. If we wish to have a non-tuberculous race, a nation stronger physically, mentally, and morally than we have ever had before, the solution of the tuberculosis problem will bring us nearer this goal.

16 WEST NINETY-FIFTH STREET

THE MEDICAL ORGANIZATION OF SICKNESS INSURANCE.

By MICHAEL M. DAVIS, JR., PH.D.,

LONDON, ENGLAND

DIRECTOR OF THE LONDON DISPENSARY

THE remarkable Report of the Judicial Council of the American Medical Association, presented last June at the San Francisco session of that body, is timely and important at a moment when much consideration is being given to extensions of the insurance idea as measures of public welfare. "In pursuit of its functions to investigate general professional conditions," says the Report, "the Judicial Council considers it a duty to bring before the Fellowship of the American Medical Association a report of certain economic conditions that are arising in this country."¹

"Some form of workmen's compensation law has been already passed in more than half the States of the Union, and there is small doubt that before long such laws will have been passed in the majority of the States if not in every one. The passing of these laws does not mean that some new or special law has been passed to compensate an injured workman under the old common law system, but it means an entirely new legal and social conception of compensation for injury and is, in fact, the beginning of a new social and economic condition in this country. These new economic conditions affect very materially the medical men in a community. It is certain to bring up the questions in new forms of contract and lodge practice, of health and accident insurance, of State aid and State medicine. It will also affect the relationship between the boards of trustees and the attending physicians and surgeons in private and municipal hospitals. Economic changes such as these must be of concern to the general profession, and the Judicial Council feels that it is timely to describe in general what these workmen's compensation laws are and what are their social and philosophic foundations, and what the trend at present seems to be in their relation to the profession."

Following this introduction, the Council's Report surveys briefly the steps taken by practically all the countries of Western Europe in providing compensation for industrial accidents, insurance against sickness, old age, maternity, etc. The Report points out that while the United States has been the last of the great nations to enter this field, the move-

ment, once started here, has been rapid, no less than thirty-three States having adopted workmen's compensation laws within the past five years. In most countries such laws, providing for compensation for industrial accidents, have been the first step, preceding the establishing of sickness insurance. The Council refers to the probability that State laws for sickness insurance will be presented to various legislatures within the next few years. "In the near future," says the Report, "the majority of medical men in this country must face a new social condition in connection with the laws of workmen's compensation in accident and probably in sickness."

"Once the old social and legal equilibrium has been upset, society tends to follow to the logical conclusion until it reaches a new equilibrium under a new social system. We have in this country a disjointed mass of insurance schemes and pensions represented by life insurance, fraternal societies, so-called industrial insurance, which is in this country but burial insurance, and health and casualty insurance. There is the huge pension fund of the United States, which has really become the old age pension of those who fought on the Northern side in the Civil War. There are various industrial pensions for invalidity and old age, as in certain railroads or in certain large industrial establishments. In several large cities in the Union there is a rapidly growing expansion and extension of activities in the health board which constitutes State medicine.

"All these, at present, form an unrelated mass, all tending to give social aid in time of varying needs, to different members of the community. In several countries abroad the same various social elements have been combined into some form of workable adaptability by which various accident and sickness insurance, invalidity and old age pensions have been brought together to form social forces which have tended to reduce the destitution of large masses of human beings. These forces unquestionably tend to improve the social condition in any given community; and for the carrying out of any scheme tending to human betterment, the medical profession must necessarily be included, whether it be to judge of sickness or health insurance, whether it be for the prevention of the intensity of injury in the individual from accident, or for the prevention of the spread of disease in the community at large."

These far-sighted leaders of the medical profession thus look forward, like many laymen, to adaptations in existing medical service to meet new social conditions. Since a bill establishing sickness insurance will be introduced into the New York Legislature in 1916, and since more than one other State will doubtless experiment with sickness insurance within the next few years, it may be of interest to consider points in which the United States may possibly avoid some difficulties which foreign countries have experienced in dealing with the medical organization of sickness insurance.

In 1911, Great Britain adopted the most comprehensive system of sickness insurance yet extant. The act came into operation on July 15, 1912. It was aimed, as the official statement says, "to provide for insurance against loss of health and for the prevention and cure of sickness and for insurance against unemployment." The emphasis upon prevention is significant. An official summary says:²

"Insurance against ill-health is compulsory under the National Insurance Act for all employed persons who were sixteen or over, and under seventy, on the 15th July, 1912, and whose rate of remuneration is not over £160 a year; and all persons (within these age limits) employed by way of manual labor must be insured whatever may be their rate of remuneration. . . . The number of persons thus insured in the United Kingdom is nearly 14,000,000, and since the Act also affects their dependants, it may be said to influence either directly or indirectly the health of three-quarters of the whole population."

"The contributions in return for which insured persons receive benefits under the Act are payable jointly by employers, insured persons, and the State, the amounts ordinarily due being weekly sums of threepence from the employer, and fourpence from insured men and threepence from insured women; the State contributing two-ninths in the case of men and one-fourth in the case of women, of the cost of benefits and their local administration, as well as bearing the whole cost of central administration."

The collection of contributions, a huge task when millions of persons are involved, is made simple by the use of insurance stamps which are affixed to contribution cards at the time of the payment of wages. The stamps are purchasable at all post offices and the employers of insured persons must put them on the cards at the proper intervals and to the right amount. The employer pays the whole amount of the contributions in the first instance, but recovers from the employee the latter's share by deducting this from his wages. Persons must ordinarily obtain insurance through the Friendly Societies, which correspond, in a general way, to the fraternal orders in this country.

In return for the insurance payments, the benefits provided for the working men and women are as follows:

1. *Medical Benefit.* Treatment in illness by a qualified medical practitioner and necessary medicines and appliances.

2. *Sickness Benefit.* Weekly cash payments of 10s. for men and 7s. 6d. for women, for a period not exceeding twenty-six weeks. The payment begins on the fourth day of an illness which incapacitates the person from working. If the insured person remains incapacitated at the end of the twenty-six weeks, a disablement benefit of not over 5s. a week is allowed.

3. *Maternity Benefit.* The payment of a sum of 30s. on the confinement of insured women or the wives of insured men.

4. *Sanatorium Benefit,* providing for care of cases of tuberculosis.

In Germany, which began with compulsory sickness insurance in 1883, the administration of the system is supervised by the State, but is left primarily in the hands of local societies, chiefly organizations formed along occupational or industrial lines. The employee contributes two-thirds, the employer one-third of the payments. Medical care is provided, and the sick benefits are based on one-half the average wages of the class of employees to which the person belongs.

In the United States there has been an enormous development of so-called "industrial" insurance, now reaching some fifteen million policy-holders in private companies. This is practically nothing but burial insurance, providing, at high cost to the insured, a fund for funeral expenses. Insurance against sickness has appeared under private auspices in a few industrial establishments. Invalid pensions and old-age pensions have been worked out in some large industries, notably certain railroads. Fraternal societies have provided for a certain proportion of the working population the questionable lodge doctor. The only satisfying and striking development in the United States, as the Report of the Judicial Council says, has been the sweep of workmen's compensation laws, or accident insurance, which has spread into two-thirds of the States of the Union within the past five years. Except for this, social insurance is in its infancy in this country. Its future lies ahead;

and in planning for this future Americans may well observe and profit by the experience of other countries.

The point of greatest difficulty in Germany and England has been the organization of the medical service for the sickness insurance. In both countries there have been severe conflicts between the insurance organization and the medical societies. In Great Britain, at the commencement of the war, there were, however, fully nine-tenths of the 22,000 physicians of the country on the insurance "panels"—that is, these 20,000 physicians were accepting insurance cases in their several districts. The doctor is ordinarily paid on the basis of so much per year for each person on his "panel." Allowance is made in addition for provision of medicines and appliances. The patient is free to select his physician from the "panel" of the district, subject of course to the consent of the doctor to act.

The financial outcome for the medical profession has been excellent. During the eighteen months following the initiation of the National Insurance Act, the payments to British physicians under the Act amounted to \$20,500,000. This was an average of \$1,150 for each physician on the "panels." The average payment per visit has worked out to be about one dollar. The average cost per patient per year for medical service for the first eighteen months was about \$1.87. "It is claimed," declares the Report of the Judicial Council, "that the insurance act has raised the level of remuneration in the profession, that the average income of physicians has been increased by from \$750 to \$2,000 a year. It seems to be the general opinion that individual physicians may have suffered and received less remuneration under this act than they formerly received under some special form of contract work; but the general amount of moneys paid to the physicians working among the industrial classes has greatly increased, and the average income of the physicians has evidently much increased."

What of the effects of the Insurance Act on the people? Previous to its passage, the situation was like that which now exists in this country. Millions of people have either no medical attendance at all or secure it only in grave emergencies. Such was the situation in Great Britain. The Insurance Act worked a revolution by making medical service accessible to the whole working population. The well-to-do classes have not, of course, been especially affected by the Act, nor have those physicians and specialists in the large cities, whose practice has been among the well-to-do.

The Act has vastly extended the reach of medical practice. It has not greatly affected the medical organization of practice, and this is its substantial defect from the standpoint of medical efficiency. The German system has been no better in this respect. Neither system has recognized the profound change which the advance of medical science has brought upon medical service. Exact laboratory methods of diagnosing many diseases have been substituted for guess-work. The applications of bacteriology, physiology and chemistry have revolutionized methods of diagnosis, treatment and prevention. The field of medical knowledge and the technique of practice in medicine and surgery, have become far too large and too complicated to be mastered by any one man. Specialists in a great variety of medical branches have been created. The general practitioner has largely lost his place

in the medical service utilized by the well-to-do. For general illnesses the wealthy call in the internist, who may be a sub-specialist in lungs or in gastrointestinal disease; for operations the surgeon, and here again a choice may be made among men each of whom gives himself to the surgery of a particular region; for a confinement, the specialist in obstetrics is called; in eye or throat trouble the oculist or laryngologist; the babies and little children of the family are under the care of a man who treats only children. The orthopedist is sought when indicated, while the laboratory worker and the x-ray man are frequently called upon to aid many of the specialists. The members of a single fairly healthy family might call upon five or six different specialists in the course of six months, while for a single obscure disease, two to ten men might be utilized. Should the patient go into a hospital, the same would be true: a group of the specialists who compose the hospital staff would work together on his case. There is, however, one essential difference between the situation in the hospital and that outside. In private medical practice the inter-relations among the various specialists, and between them and the patient, are not organized, except through those mutual understandings between physicians which are crystallized in certain sections of the code of medical ethics. In hospitals and dispensaries, on the other hand, these relations have been organized. Moreover, in private practice each physician has his independent equipment in his office, or depends for laboratory and x-ray work upon the offices of other men, who are remunerated for each case. In the hospital or dispensary there is organization of equipment as well as of personnel; duplication of instruments and apparatus is avoided, and each unit is put to the maximum use. It is, in fact, to the hospitals and dispensaries that we must turn to-day if we are to study medical service at its best.

The principle under which the medical organizations of the best general hospitals and dispensaries are organized is that of medical teamwork. In such varied institutions as the factory, the university and the hospital, we see exemplified the now familiar principle that specialization is necessary to the maximum of efficiency and that specialization requires organization if this end is to be achieved. The medical care of a patient includes two essential stages: the establishment of a diagnosis and the carrying out of treatment. In both stages the co-operation of specialists is important, but particularly in making the diagnosis. Even where the diagnosis is readily established, treatment often requires one who is especially expert in a particular service. When, as is not infrequently the case, several different specialists are needed for a single patient, their co-operation in working together is of the highest importance. Confusion in the mind of a patient in private practice today is not infrequent and the expense to the patient is enhanced by lack of organization.

The modern hospital is an institution for the organization of specialists for the care of patients who are sick enough to be in bed. These specialists utilize equipment in common. A dispensary similarly is an organization of specialists for the treatment of patients whose diseases do not prevent them from going out to see the doctor, that is, ambulatory cases. The relation between the hospital and dispensary from this standpoint is essentially that between the practice of a private

physician in the homes of his patients and at his office. A dispensary is essentially an organized system of office hours; a hospital, an organized system of caring for patients in bed.

The advances of medical science have enormously increased the technical equipment necessary for the diagnosis and care of disease. Merely mentioning modern requirements of laboratory and x-ray service, not to speak of operating facilities and instruments, is enough to illustrate the point. This elaborate equipment is beyond the reach of the individual physician, even those dealing with the well-to-do. The hospital or dispensary can provide equipment for the use of many. Through organization it saves the time which physicians and particularly specialists spend between the intervals of seeing patients. An organization such as the famous Mayo Clinic at Rochester, Minn., exemplifies a dispensary organization which has been most carefully worked out with the maximum of medical as well as business efficiency in mind. Seventy-five picked men constitute its medical staff. The organization of the whole clinic is designed to aid in establishing diagnoses of disease and in providing or supervising its treatment by organizing the teamwork of its specialists with a minimum expenditure of time and maximum utilization of scientific aids to medical work. It also minimizes through organization, the confusion to which contact with a variety of specialists often leads in private practice among the well-to-do.

The same principles can be seen illustrated in the best dispensaries managed by charitable institutions and treating patients free or for nominal charges; and in the best hospitals giving care to bed cases.

Hospital service in America has developed enormously within recent years; dispensary service at an even faster pace. A million persons now receive treatment in hospital beds annually in the United States, and three million ambulatory cases are treated in dispensaries. The number of dispensaries has increased at least seven-fold in the last fifteen years. A report published in 1914 by a Committee of the American Hospital Association may be quoted:

"In 1900 there were about 100 dispensaries in the United States, 80 to 90 of these being general dispensaries. The number increased, year by year, with considerable rapidity, so that, in 1904, the Census Bureau, which then made a survey, reported 156 institutions, the actual number, allowing for probable omissions, being toward 200. Most of these, again, were general dispensaries, the remainder being for diseases of special organs, chiefly eye, ear, nose and throat. The growth of general dispensaries has continued, as may be seen from the preceding figures, the number of these having multiplied four times since 1900 and two and a half times since 1904.

"One of the reasons for this growth has undoubtedly been the increasing demand of medical men for clinical material, both for experience and for teaching purposes. Another reason is the growing demand on the part of the public, particularly the part of the public receiving low wages, which, in the large cities, has been put under heavier and heavier pressure by the rising cost of living. A third and very important reason is the growing interest in public health, which has taken up the dispensary as an agent in its campaign. This has undoubtedly played some part in the development of dispensaries treating general diseases. It has been the chief cause leading to the establishment of a very large number of out-patient clinics treating special diseases, particularly tuberculosis."

The justification of these references to the development of dispensaries and hospitals lies in the

fact that until very recently this development, particularly that of dispensaries, has been little called to the attention of the public. The application to the problem of sickness insurance is not far to seek. If a system of sickness insurance is to provide medical service for a large part of the working population on the financial basis provided by insurance payments, surely the medical organization of the system ought to be in line with the most advanced forms of medical work; or at least the system should contemplate development in that direction. Neither the British system nor the German organizes the medical service beyond the stage of individualistic private practice. The British system has failed to utilize the important existing centres of medical organization provided in the larger cities by the hospitals and dispensaries. Before sickness insurance was established in Great Britain, three years ago, a great part of the population suffered from a lack of medical service. It is a great gain to have met this deficiency but much still lies ahead. America should build upon foreign experience and go Great Britain one better. The developing movement for sickness insurance in the United States should provide or look forward to the best form of medical organization.

Practical suggestions to this end must be considered. Conditions of medical service in smaller communities or in rural districts are so different from those in cities that it is unwise to expect uniformity of system throughout. Within the boundaries of a single State such as New York or Massachusetts, conditions vary over such a wide range that a state system of insurance ought to provide for local variations and be sufficiently flexible to admit of development as local communities themselves advance.

In the larger centres the existing facilities of the hospitals and dispensaries ought to be utilized by the sickness insurance system. The dispensary is of especial importance to sickness insurance because its special field is prevention. Serious diseases in their earlier stages, minor diseases which sap vitality or reduce working efficiency, serious but not incapacitating diseases such as syphilis, gonorrhea, various diseases of the throat and other special organs, are examples which fall within the special field of the dispensary. People need to come to the doctor earlier so they may be kept at work or at least be sent back to work with a minimum of lost time.

The task of organization here is a large one. Experiments are now in order to test out various methods, each of which may be applicable to one or another set of local conditions. For example:

In the German and in English sickness insurance systems, voluntary organizations (such as are known in this country as trade unions, fraternal orders or establishment funds including the employees of a particular company) are allowed to make their own insurance arrangements with medical men under the supervision of the State Insurance Department. Undoubtedly, under any sickness insurance plan adopted in America, such approved societies would be similarly recognized. Such societies should be allowed to make contracts for their medical services under the insurance system with a dispensary or hospital. The physicians who provide the medical service through the medium of the institutions should receive the same compensation as the physicians who work outside as individuals.

Time and money will be saved if the care of

patients who do not require confinement in bed can be so organized that the patients come to the doctor instead of the doctor traveling to the homes of the patients. This means either at the offices of the doctors or at a central place, namely a dispensary, to which the ambulatory cases come. Enough has already been said in this paper on the advantage of so organizing the service that the material and personal equipment of the dispensary can be used for these ambulatory cases. Merely utilizing the individual practitioner and therefore requiring many visits at the homes for the treatment of ailments which do not confine the patient to the house, is not economical and is not the most efficient medically, even disregarding its extra expense. The utilization of a dispensary also provides for the services of a medical team of specialists, but it would be decidedly unfortunate to utilize the dispensary for such specialists' services only. Existing dispensaries should be adapted or new dispensaries established to meet the conditions of the insurance system.

A large part of the sickness insurance is necessarily carried by other than the voluntary societies previously referred to. In this country these groups will necessarily be local associations of the insured persons. Such local health associations may, like the approved societies, make arrangements with an existing dispensary and hospital, or with an organized group of doctors who might either start a dispensary or arrange to utilize the equipment of one already established. By organized group of physicians is meant a body of men who have so selected themselves as to include a variety of medical interests or specialties, and who have agreed to work as a team rather than as individual practitioners.

Under the British and German insurance systems, persons above a certain grade of income are allowed to take sickness insurance as so-called "voluntary insurers," while all persons having less than a specified minimum income come under compulsory insurance and must join. Voluntary mutual insurance groups should be encouraged. The strongest encouragement, so far as sickness insurance is concerned, will be the possibility of securing high grade medical service at lower cost than would be possible without co-operation. Abroad, the voluntary insurers have been relatively few in number. In the United States there is a growing recognition of the difficulty with which the middle classes—professional men, small business men and moderately salaried positions of all kinds—can secure enough of the same kind of medical service which is now open to the rich and to the poor. By co-operation on the part of the patients, making up a volunteer insurance group, such a service could be financed; and by co-operation on the part of the physicians using the principle of medical teamwork and a joint diagnostic equipment, the service could be made medically efficient. If such an economic inducement can be offered to the middle classes, we may perhaps hope for the development of many voluntary health insurance groups.

To test out methods of medical service on the teamwork plan through such voluntary groups is of high importance. Either the equipment afforded by an existing hospital or dispensary, or that newly provided by a group of doctors associating themselves co-operatively, should be utilized. The former would usually be the more economical plan, the latter might better fit localities where hospitals

and dispensaries are poorly developed, and would meet the prejudice of those who have been accustomed to think of hospitals and dispensaries as only for "objects of charity."

In summary, the argument of this paper leads to the suggestion that a sickness insurance law should permit medical service on *either* the co-operative or the individualistic basis. The sickness insurance system should of course enable the present British plan to be followed of utilizing individual physicians (or the members of a district medical society) on a panel system, but as an alternative plan, it should also allow and encourage local societies or associations of the insured to make suitable arrangements for medical service with a dispensary or hospital, or if necessary, to establish such an institution. Only by utilizing a joint diagnostic and therapeutic equipment, and the teamwork of a group of physicians, can the maximum service of modern medical science in the cure and prevention of diseases, be made financially accessible to the mass of the community.

MERCURY ELIMINATION IN BICHLORIDE POISONING.*

BY KARL M. VOGEL, M.D., AND O. IVAN LEE, B.S.,

NEW YORK.

MEDICAL literature abounds in references to the elimination of mercury after prolonged courses of treatment by this agent, and in reports of the results of analyses performed on the organs of persons dying from acute or chronic mercury poisoning. Few studies are to be found, however, relative to the important subject of the manner in which the living body disposes of the drug in cases of acute poisoning, largely, perhaps, because the classical methods of analysis are too time-consuming to permit of their use in the routine daily examination of the excretions for the periods of weeks or months sometimes necessary. By means of the method of testing for mercury developed in this laboratory¹ it has been possible to study in detail the channels by which the poison leaves the body, the time that is required for its complete removal, and other facts in regard to its elimination, all of which have been utilized by Drs. S. W. Lambert and H. S. Patterson in formulating a plan of treatment for these cases, with extraordinarily good results. Full details as to the theoretical considerations on which the treatment is based and the technique of its application are to be found in a recent article by these two authors.² During the period from January, 1914, to December, 1915, sixteen cases of bichloride poisoning have been treated in St. Luke's Hospital with only two deaths. The full clinical histories of many of these, with complete records of urinalyses, etc., are contained in the above mentioned contribution by Lambert and Patterson, and in the present communication it is the purpose only to mention briefly certain points not generally recognized.

*From the Pathological Laboratory of St. Luke's Hospital, New York, Dr. F. C. Wood, Director.

In the first place, our experience with these cases shows the advisability of making frequent routine tests on the urine, stools, stomach washings, and colon irrigation fluid in order to determine when it is safe to discontinue the treatment, and also to avoid protracting it unnecessarily. The fact that for a certain time mercury is re-excreted into the stomach is of importance, for by regularly repeated gastric lavage one interrupts the vicious circle of excretion and reabsorption and removes from the body a certain portion of the poison which otherwise would have to find egress through the kidney or bowel, with a consequent increase in the risk of serious damage to each of these structures. While ordinarily excretion by the gastric route ceases before it does so from the kidney and bowel, this is not invariably so, as is shown by case No. 11 of the table, in which mercury persisted in the stomach washings two days longer than in the urine or feces. That this fraction of the mercury is really excreted by the stomach wall and does not reach the organ through swallowing saliva or by regurgitation from the duodenum is demonstrated by the experiments of Lieb and Goodwin,³ who found the metal in the stomachs of cats poisoned by the subcutaneous injection of bichloride, even though the esophagus and duodenum had previously been ligated. In this connection it is of interest to note that in case No. 13 mercury was recovered from the stomach washings, although the poisoning was effected by inserting half of a bichloride tablet into the vagina. Another point of interest is the length of time during which elimination proceeds. As will be seen from the table it is extremely variable and may be protracted to an astonishing degree, as in case No. 3, in which after a single dose of four tablets the mercury could still be recognized in the excretions more than three months later, in spite of the fact that the patient vomited promptly after taking the poison and reached the hospital within less than three hours. This patient suffered from almost complete suppression of urine for about a week, and that the renal efficiency was greatly reduced is shown by the low phthalein excretion, so that one's first impulse is to attribute the delayed excretion to this fact. The next patient in the series, however, No. 4, who also took four tablets, did not suffer from suppression of urine and her phthalein excretion never fell below 62 per cent., still with her also the excretion dragged along for more than eighty days. Yet in her case the conditions for the production of renal injury were apparently more favorable than in the preceding one, for she took first one tablet four days before admission to the hospital, two more on the day preceding admission, and the fourth on the day of admission, so that she did not reach the hospital till more than four days had elapsed after swallowing the first dose. The rate at which the drug is eliminated would seem to depend on some factor not yet understood, for a careful study of the histories of the cases shows that neither the size of the dose, the interval before the stomach is emptied by vomiting or lavage, nor the delay before treatment is begun by antidotes or the institution of eliminative measures have any definite significance in this connection. No doubt the mercury enters into combination with the protoplasm of the body cells and is held fixed by these until they disintegrate, but why this should take so much longer in some cases than in others is not easy to explain. An observation of much interest is the fact that in eleven of the six-

TABLE I

Case No.	Patient's Name	Date of Admission	Date of Last Positive Test for Hg.	Vomitus	Gastric Lavage	Stool	Urine	Sweat	Blood	Hg. Persistent Longest in	Days Before Elimination Complete	Result	Amount Taken	Remarks
1	C. P.	1914 January 23	1914 January 28	-	+	+	-		0	Stool	6	Cured	2 tablets.	
2	W. A.	March 3	March 10	+		+	+		0	Stool	8	Cured	1½ grains.	
3	H. B.	March 26	July 6	+	+	+	+			Stool	104	Cured	4 tablets.	Almost complete suppression of urine for 5 days. Phenolsulphonephthalein excretion; April 7, 3.3 per cent May 10, 71.4 per cent.
4	R. H.	April 9	July 2		+	+	+			Stool	85	Cured	4 tablets taken over a period of 4 days.	No suppression of urine. Phenolsulphonephthalein excretion never below 62.5 per cent.
5	E. N.	June 14	July 28	+	+	+	+			Urine	45	Cured	5 or 6 tablets.	Elimination not complete.
6	E. M.	July 11	July 22			+	+			Stool	12	Cured	1 tablet.	
7	V. W.	November 20	December 15	+	+	+	+			Stool	27	Died	An unknown amount.	Urine last positive for Hg. on Dec. 1. Suppression of urine 1 week. Phenolsulphonephthalein excretion: 13 per cent.
8	A. B.	December 29	January 6		0	+	0			Stool	9	Cured	1 tablet.	Neither urine nor lavage fluid were ever positive for Hg.
9	E. W.	1915 January 17	1915 January 29		+	+	+			Stool	13	Cured	Part of a tablet.	
10	E. S.	March 21	April 1		+	+	+	+		Urine	12	Cured	3 tablets.	
11	M. D.	May 2	May 8		+	+	+	+		Lavage	7	Cured	1 tablet.	Urine and stool both negative, May 7th and 8th.
12	A. S.	July 15	August 2	+	+	+	+		+	Urine	19	Cured	1 tablet.	Sputum positive on July 19. Spinal fluid negative. Last positive test on stool July 27th.
13	W. L.	August 23	August 30		+	+	+			Stool	8	Cured	2 tablet introduced into vagina.	Spinal fluid negative.
14	V. B.	September 28	October 13	+	+	+	+	0	0	Stool	16	Cured	1 tablet.	
15	C. W.	November 15	December 7		+	+	+			Stool	13	Cured	Part of a tablet.	Elimination not complete.
16	W. M.	December 10	December 15	+		+	+	0	+			Died	4 tablets in solution.	Spinal fluid negative. Throat irrigation positive. Almost complete suppression of urine on last four days, with nitrogen retention in blood.

teen cases the mercury persisted longer in the stool than in the urine or stomach washings, and in two at least of the remaining five elimination was not complete when the patient left the hospital, so that possibly longer observation might have shown that this patient also belonged with the majority. A

further observation bearing on this point was made on a case outside the hospital in which only a single examination was done, and which is therefore not included in the table. This patient was a woman who had been using frequent (often several times a day) douches of bichloride, the exact strength of which was not ascertainable, and developed a severe bloody diarrhea. Specimens of stool and urine were brought for analysis two weeks after the last douche had been used. Mercury was present in the stool, but not in the urine.

Attention may also be called to the fact that in two of the four cases in which tests were made for the presence of mercury in the sweat, elimination of the poison by this route could be demonstrated, showing the advisability of employing hot packs as part of the treatment. In five tests made on the blood of four patients only two proved positive, and in three cases in which the spinal fluid was examined the result was negative, an observation quite in harmony with the well-known impermeability of the meninges and choroid plexus to the passage through them of drugs. Blood nitrogen determinations were made in only three of the cases. In one instance (No. 14) a curiously low result was obtained: non-protein nitrogen, 16.6; urea nitrogen, 8.6, with a phthalein excretion of 62.5 per cent. In another case (No. 12) the non-protein nitrogen was 31; urea nitrogen, 15; urea, 5.4; creatinin, 1.2, and the phthalein 45 per cent. In the third case (No. 16), which terminated fatally, the non-protein nitrogen was 100, the urea nitrogen 71.5, the uric acid 5, and the blood sugar 50, the figures, as usual, expressing milligrams per 100 c.c. of blood.

That some discretion should be exercised in the external use of bichloride solutions for surgical dressings is shown by the fact that mercury may be

TABLE II

				18,500	78	22	

detected in the excretions a few hours after the application of a wet dressing of this antiseptic. In one instance a 1:10,000 bichloride dressing was applied to the left elbow of a patient suffering from osteoarthritis, the skin being broken over an area a few centimeters in diameter. Mercury was found in the stool on one occasion, but not in the urine in spite of repeated examinations. In another case a 1:5000 bichloride dressing was applied to the elbow, the skin being intact, and the urine and stool both showed the metal for two days following.

The behavior of the leucocytes in bichloride poisoning is interesting and deserves further study. In nearly every case, as will be seen from the table, a leucocytosis appears early, subsiding again after a variable period. This is usually in the nature of a polynucleosis, especially when a high total count is observed, as, for example, in case No. 6, in which the high figure of 70,000, with 92 per cent. of polynuclears was reached, falling in four days to below 20,000. This phenomenon does not appear to be generally recognized, but should be kept in mind in order to avoid the chance of unnecessary surgical intervention in the presence of abdominal pain, vomiting, high leucocyte count, and an unsatisfactory history if there should be a possibility of acute bichloride poisoning either accidentally or by design.

Conclusions.—1. The elimination of mercury in cases of acute bichloride poisoning may continue for periods of time ranging from a week to several months, and treatment should be continued until it has been shown that elimination of the drug is ceasing. The excretion usually continues longest from the bowel, and systematic flushing of the large intestine should always be carried out, but the gastric mucosa and the skin are also important as channels of elimination and should be utilized in order to spare the renal epithelium.

2. A considerable leucocytosis with an absolute and relative increase in the polynuclear cells is practically always present.

UNILATERAL HYDROCEPHALUS.

By EDWARD LIVINGSTON HUNT, M.D.

NEW YORK.

INTERNAL hydrocephalus is not uncommon; unilateral internal hydrocephalus is uncommon, the usual distribution of fluid being to all the ventricles of the brain. The case which follows is one in which the hydrocephalus was limited to the left lateral ventricle. The cause of these ventricular accumulations of fluid is still obscure. Many are due to an obstructive lesion affecting the patency of the foramen of Monroe. Many are due to an obstructive lesion, probably tubercular, situated in the choroid plexus. Some are due to a gliosis of the Aqueduct of Sylvius, and more recently the work of Dandy and Blackfan has shown a type of hydrocephalus in which the channels are patent, the hydrocephalus being due to the diminished absorption from the subarachnoid space.

It is greatly to be regretted that this report must be so incomplete, and that it cannot trace the etiology of the condition, or give any of the microscopic findings. My thanks are due to Dr. A. W. Hollis for the privilege of reporting it.

Many have assigned reasons to explain the causes

of these hydrocephalic conditions, but few have been fortunate enough to have had an opportunity to observe the patients with any care and detail before death. The following case was under close observation for some time; its report may, therefore, prove of some value.

Touche has reported a case of hydrocephalus which developed convulsions, an increase in the size of the head and finally a paralysis of both sides of the body. The autopsy showed both lateral and third ventricles dilated.

W. C. White reported a case of unilateral hydrocephalus in which a woman of seventy-four years had frequent attacks of hemiplegia. The autopsy showed unilateral internal hydrocephalus. Here there was an obstruction in the choroid plexus.

Spiller reported a case of unilateral hydrocephalus in which a child of fourteen developed bilateral contractions and muscular atrophy. The autopsy showed a unilateral hydrocephalus due to a partial closure of the right foramen of Monroe.

Mrs. C. was seventy-eight years old. She complained of headache and pain in the legs and feet. Twenty-five years before she had met with a shock, which had left the left side weak. She had recovered sufficiently so as to be able to use her hands and to walk. Her headache had been severe and of some weeks' duration. She was somewhat deaf, the urine was scant and light colored. There were times when she lost consciousness for several hours. No nausea or vomiting. The family history was not very illuminating. Her father died of Bright's, mother of consumption.

The previous history was unimportant. She denied syphilis; had had no miscarriages; was the mother of one child and was a moderate tea drinker. Lately she had lost some weight.

The patient was poorly nourished and looked chronically ill. The pupils were normal, there were no enlarged glands. The thorax was symmetrical, with good expansion. The heart action was regular and rhythmic. There was a faint systolic murmur heard all over the precordium. No accentuated sounds. The lungs showed nothing, but coarse moist râles all over the chest. The abdomen was negative, the liver and spleen not being felt. The patient had an attack of psoriasis. The knee jerks were present, there was neither ankle clonus nor Babinski. The pulse was regular and rhythmic. The arterial walls appeared moderately thickened.

The urine was 1.015 specific gravity, with a faint trace of albumin, no sugar, and many leucocytes and epithelial cells, and a few hyaline casts. Vaginal and rectal examinations revealed nothing. The Wassermann was negative. The blood examination showed 85 per cent. hemoglobin, with 6,500 white blood cells, polynuclears 37, lymphocytes 63. The blood pressure was 130-190.

The eyes as examined by Dr. Wiener: The upper edge of each disc was slightly indistinct. In each eye several of the arteries appeared narrow and pale, and in two or three places there seemed to be an interruption in their continuity. The veins looked a little congested.

The ears as examined by Dr. Dench: Both drums appeared retracted; there was congestion around the handle of the malleus.

The patient entered the wards on September 14 and that night was seized with convulsive movements of both arms and legs. These attacks continued with more or less severity for several days. A lumbar puncture was made, the fluid was clear, there were two cells, the Wassermann and the butyric acid tests were negative. The amount of urine passed each day varied from about 20 ounces to 35 ounces. Under mild sedatives and diuretics, she improved somewhat and sat up. At the end of two weeks she complained of pain in the back of her neck, and began to have difficulty in speaking correctly. She then began to behave queerly, soon becoming irrational and violent.

A few days later occurred an attack of cyanosis with general twitching and on October 17 she developed a general convulsion. On October 21, when the urine was 33 ounces, she had a very severe attack of cyanosis, in which she became rigid with an imperceptible pulse.

These attacks of cyanosis and twitching became more

and more frequent, recurring, as often as every hour. Finally, she died in one of these attacks.

Autopsy: By Dr. K. M. Vogel. The pupils are equal, and both react. Patient has psoriasis.

Heart: The valves are slightly thickened and there is moderate atheroma about the aortic ring. The coronary vessels are sclerotic, but not thrombosed. Mitral valve is moderately thick and stiffened. Orifice measures 9cm. Wall of the right v. measures 2 cm. Pulmonary valves show no abnormalities. Tricuspid slightly thickened.

Lungs: Left lung is voluminous and does not collapse. At the apex is a large and depressed cicatrix, with fibrous prolongations into the lung substances. On incision the upper lobe is found emphysematous, but dry. The rest of the lower lobe is also emphysematous, but the posterior portion contains much fluid, and from the bronchi much purulent secretion can be squeezed. The bronchial nodes are anthracotic, but not calcareous. The right lung is adherent at the apex, where there is an old cicatrix and in general appearance resembles the left. Upper and lower lobes show the same changes as in the left.

Spleen is extremely small, measuring only 4.5 by 2.5 by 1 cm. but it has the typical form of a normally developed organ. On incision the pulp appears normal.

Left kidney shows fetal lobulation; the capsule strips fairly well. The cortex is of uneven thickness, the surface is granular, the markings poor. The blood-vessels are somewhat thickened.

Right kidney resembles the left, except that it shows numerous cicatricial depressions where the capsule is thickened. The appearance of the parenchyma is like that of the left kidney.

Heart weighs 250 grams; left lung, 250; right lung, 250; left kidney, 100; right kidney, 75; liver, 925 gm.

Liver is small, surface is small, but the peritoneum is thickened over the anterior edge of the organ. On incision the parenchyma is seen to be somewhat mottled and is glassy in appearance.

The gall-bladder contains brownish bile, little mucus, and no calculi. Pancreas appears somewhat fibrous. Aorta shows extensive atheroma with calcification. Bladder, uterus, and ovaries show no abnormalities.

Brain: On removing the skull cap, the dura is seen to be much discolored over the parietal and posterior portions on the right side. On incising it there are found the remains of an old hemorrhage covering an area several centimeters in diameter. The surface of the pia is smooth, but there is an extensive infiltration of cerebrospinal fluid over the entire surface of the brain. The meningeal vessels on the right side are much congested. All of the vessels at the base of the brain are sclerotic. On opening the organ it is seen that the lateral ventricle on the left side is much dilated, especially in the occipital region and is distended with clear fluid. Sections through the brain show that the vessels throughout its substance are everywhere congested.

Diagnosis: Bronchopneumonia; subdural hemorrhage; cerebral arteriosclerosis; dilatation of the lateral ventricle; edema of the brain; atheroma of the aorta; endocarditis (initial); parenchymatous degeneration (fifth degree) of liver; chronic diffuse nephritis; psoriasis; chronic adherent peritonitis about the cecum; micro-spleen.

41 EAST SIXTY-THIRD STREET.

THE HIGH FREQUENCY CURRENT IN THE SERVICE OF THE GENERAL PRACTITIONER.

BY LOUIS COHN, M.D.,

NEW YORK.

THOUGH I have employed in my practice of over thirty years the galvanic and faradic currents, mostly in gynecological work, I have in the last five years used the high-frequency current in so many different diseases and with such success that I feel I ought to publish some of the rather striking cases and the results obtained.

I shall begin with some cases of nervous disorders, the following being one of obsessions:

CASE I.—A young man of 24 years, a bookkeeper,

was sent to me by his employer for treatment. This young man, about 9 months before consulting me, was present at the death of his grandfather, which scene impressed itself to such an extent upon him, that he could not rid himself of this picture. After a few months it affected him so that he could hardly eat or sleep and finally was on the point of abandoning his work, not being able to concentrate his thoughts on it. He had sought the aid of a number of physicians, without being in any way benefited by their advice and treatment. On examination I found no physical defect, beyond this disturbance of the nervous system. He was rather unwilling to take any medicine as he claimed to have swallowed an ocean of it without benefit, but on assuring him that in conjunction with electricity it would bring about a cure, he finally consented to take a mild sedative. He received about 25 treatments in the form of autocondensation, which resulted in an absolute cessation of these delusions, and though three years have elapsed, no recurrence has taken place.

I have had two more cases of this nature, one of which has been restored to a normal condition, the other, though greatly improved, abandoned treatment on account of leaving the city. While such cases of psychopathy offer greater difficulties than the ordinary nervous cases we usually have to deal with, they react generally just as favorably. There is, however, no doubt in my mind that while the electricity is a great factor, the personal element in the form of suggestion adds considerably to the successful treatment in such severe cases.

And now let us consider the rationale of this treatment, which many physicians not alone do not believe in, but reject as absolutely worthless. Whatever the primary cause of these nervous disturbances may be, whether brought on by shock, worry, abuse, disappointment, overwork, etc., unless the condition soon ceases, we have in course of time a progressive involvement of the functions of all the organs. If we consider the nervous system the balance wheel of the body, we can readily understand why, with the lack of harmony and rhythm in the different organs, they themselves become secondarily victims of this condition. We speak of nervous dyspepsia, nervous palpitation of the heart, nervous intestinal derangement, extending to the urinary organs. We finally see the process of metabolism involved and both assimilation and elimination affected. This again brings about a condition of autotoxemia, a poisoning of the whole system; and here we have our vicious circle complete.

Now what does high frequency treatment do for such cases? In answering this question now, we shall see later on why this current is of great use in all cases where there has been a disturbance of the physiological processes of the body, whether in the circulatory, the secretory, the excretory, the respiratory, or the cutaneous system. The primary effect of this current is an increase of the metabolism of the body by improving nutrition and furthering elimination. This we may call the framework of our therapeutics, and if we add to this the vitalizing effect it exercises upon the circulatory system as well as its tonic action upon the nervous system, we have here a quartette of beneficent actions which no other therapeutic measure presents in a single form.

While some of our critics see nothing but concentrated heat in the high frequency current, which in itself is quite a useful therapeutic agent, we know from actual facts that through its dissemination of ozone it has both an antiseptic as well as oxygenizing effect. Besides mentioning the use of this current in the destruction of bacteria in the water, we

have the records of many authorities who have employed it for the development of plant life as well as for bringing about an improvement in the mental and physical life of children.

These various statements made by me in regard to the action of the high frequency current upon the physiological as well as upon the pathological process of the body, are discussed elaborately by S. H. Monell, M.D., in his text-book on "High Frequency Electric Currents in Medicine and Dentistry." Though some of his statements are considered by many as not entirely proven, my experience and the successful results following the use of this current in my practice leave no doubt in my mind that he is guilty of no exaggeration and that he is absolutely within the confines of truth and verifiable facts.

I am able to illustrate this phase of the current with a concrete example in the following case:

CASE II.—Mrs. D. A., 59 years old, consulted me in regard to her extreme nervous condition, poor sleep, lack of appetite, sour and bitter taste in the mouth, and loss of weight amounting to 40 lbs. in 2 years, following an abscess of the right leg which confined her to bed for 3 months. A physical examination showed no lesions of any kind, except a moderate anemia. Treatment by very competent authorities had been without success, and she found herself now in a condition where life had become a burden. She was given an iron tonic and received the autocondensation treatment 3 times a week. She gained steadily in weight, the first month 4 lbs., the next 3 lbs., etc., and at the end of nearly 5 months her weight had increased 20 lbs. She weighs as much now as she ever did, has been perfectly well all these years, with all her functions in absolutely normal condition.

It is but fair to assume in this case that during her sickness a systemic absorption of toxins had taken place, which produced this nervous condition and also interfered with her metabolism, bringing about the loss of weight. The current by its oxygenizing power furthers all metabolism, and by improving both assimilation and elimination removed the toxemia, placed her nervous system in a normal condition, and restored her weight.

Here follows a case of vasomotor disturbance:

CASE III.—Mrs. M. E., 65 years old, complained of frequent tingling of finger tips and a loss of tactile sensation, making it impossible for her to use a sewing needle and even making it difficult for her to hold a spoon, knife, etc., in her hand. She received autocondensation treatment 3 times a week for about 4 months, which restored all her functions to a practically normal degree.

As an incidental result of the treatment the patient claimed that her hearing had been greatly benefited, a statement which was also made by a gentleman, 78 years old, who had been treated for arteriosclerosis. While, however, it is evident that an improvement follows in such cases where there is a functional impairment of the auditory nerve, I have had no favorable results in two cases where a progressive diminution of hearing was due to a sclerosis of the middle ear.

CASE IV.—Mrs. L. C., 42 years old, woke up one morning, not to find herself famous, but to find that she was cross-eyed, which I considered, after careful examination, to be a case of hysterical strabismus. A further examination of the eyes by an oculist revealed no intraocular changes, confirming my original diagnosis. About 6 weeks of autocondensation treatment followed up by the glass vacuum brought about a complete restoration of the affected functions and improved greatly her general condition.

As pruritus is commonly considered an affection due to a disturbance of the nervous system caused

by some systemic conditions, I shall present here three varieties of cases in which the high frequency current brought about a rapid cessation of that incessant itching which makes the life of its victim miserable.

CASE V.—Mrs. M. R., 32 years old, of a very neurotic past history, had been suffering for a few days from a general pruritus; there was no cutaneous lesion of any kind and no organic cause detectable. The pruritus was considered by me as being of a purely nervous origin. She received about 3 weeks of daily autocondensation treatment which, as she said, made "life worth living for her once more."

CASE VI.—Mr. S. C., 72 years old, a victim of senile pruritus, had consulted a number of skin specialists, but in spite of external medication and a great variety of local measures, he itched and scratched day and night. He was in a most pitiable condition when I saw him, and had abandoned all hope and all faith of ever being freed from his tortures. Though this case was a very severe one, 3 weeks of daily autocondensation improved the condition marvelously, and though it required many months, treatments given 3 times and then twice weekly, to bring about a complete cure, he has had hardly any trouble these last years.

CASE VII.—Mrs. A. C., 64 years old, had been troubled with itching of the vulva for several weeks before consulting me; an examination of the urine showed almost 3 per cent. sugar—a case of diabetic pruritus. About 4 weeks of autocondensation, each seance followed by 5 minutes of glass vacuum treatment, did away with the itching and the diabetes. Concerning the latter I shall have something more to say later on.

It is clear that in these cases the current had not only a sedative and anodyne effect upon the nervous system, but a reconstructive and eliminative effect upon the whole metabolism. I shall not speak at length of these innumerable cases of neurasthenia, nervous agitation, that motor restlessness which sometimes takes hold of even the stoics, nor of those cases which suffer occasionally from the "blues," but I shall prescribe for them some autocondensation treatment with its stimulating effect, the veritable electrical "cocktail."

Let me now review a few cases in which the trouble was due to a lack of elimination of those toxins which are the foundation of rheumatism, gout, neuritis, and neuralgia, and which resist often enough even the best medical treatment. Rheumatism and gout, as well as neuralgia, yield readily to the autocondensation, sometimes followed up locally by the glass vacuum electrode; but when we have to deal with a case of neuritis we are obliged to have recourse to the diathermic treatment, which in its efficiency has absolutely no rival. Wherever this treatment in my hands failed to cure the patient, it was found that the neuritis was not due to a simple local inflammation of the nerve, but was based upon some systemic condition, as a tumor pressing upon the nerve trunk.

Here are a few varieties of severe neuritis, with their histories and successful treatment:

CASE VIII.—Mr. D. S., 72 years old, came to me with a history of tic douloureux, for which he had received an alcohol injection; this for the time being abolished the pain, but produced a partial lockjaw, evidently due to traumatism, which, in spite of several months' massage treatment, had not improved whatever. A proposed operation to remedy this condition was declined. The patient, though not of a very hopeful nature, was satisfied to take treatment, though I could not assure him of how much I was able to benefit him. I used the diathermic current daily in the beginning, and within 2 months brought about a complete cure of the lockjaw. After about 4 weeks of treatment the pain in his liberated nerve started again, though not in quite as severe a form as before. With the continuance of the treatment, however, the pain ceased and returned only to

a very moderate degree during the next year, to be easily controlled by a few treatments.

CASE IX.—Mr. A. N., 52 years old, consulted me in regard to a sudden paralysis of one side of the face, involving the eyelids, a typical case of Bell's paralysis. In spite of my earnest advice to have him take treatment at once, he was not able to do so on account of an important business trip to the West. He consulted a physician there, who told him not to do anything about it, as these cases generally get well without treatment. As in most cases, patients very readily accept such an advice, he let nature take care of it, with the result that on his return 6 weeks later the condition was absolutely unchanged. It required about 2 months of daily diathermic treatment and faradism to the affected side to restore the nerves and muscles to an absolutely perfect condition.

Incidentally the patient revealed the fact that as a result of the treatment he had gained greatly in sexual power, a statement made also by another gentleman whom I treated for arteriosclerosis. I have not used this current specially for this purpose, but have no doubt that with its stimulating effect it could be made useful in cases of sexual weakness.

While the use of massage and electricity is always indicated in cases of paralysis following cerebral hemorrhage, after the acute attack has passed I have employed in the early stages of a number of cases the glass electrode of a portable high frequency machine with admirable results, following it up later with the autocondensation treatment.

CASE X.—Mrs. B. L., 44 years old, suffered excruciating pain in her left arm, and though she had been under treatment of an osteopath for many months and had also subjected herself to the baking process for some time, her pains were as severe as ever, tormenting her day and night. It required several months of continuous diathermic treatment to restore her to a normal condition, free from pain and able to use her arm fully.

CASE XI.—Miss E. C., 28 years old, a nurse, had been suffering from neuritis of the right arm for over 2 years. Being attached to a hospital, she had the advice of a number of physicians, but in spite of it found no relief and was brought to a point where she was almost unable to use the arm. Several months of diathermic treatment brought about a complete cure, the full use of her arm.

In spite of the fact that I heard a gentleman who uses this current in his practice say that he was not able to get results in sciatica, I have had gratifying results in a number of cases, of which I shall quote here the following:

CASE XII.—Mr. M. G., 45 years old, a commercial traveler, was obliged to return from his trip on account of severe pains in his left hip. An examination showed the maximum of pain over the sciatic notch radiating toward the knee and increased by any movement overstretching the nerve. It required but a comparatively short time to mitigate the severity of the pain by using the diathermic treatment followed by the glass vacuum electrode. He continued this treatment for several weeks, when he was discharged entirely freed from all pain.

Though I have still a predilection for the use of the galvanic and faradic currents in gynecological cases, I have employed with pronounced success the diathermic high frequency current in several cases of ovarian neuralgia, stimulating in two cases original attacks of appendicitis, lacking, however, rigidity of the muscle and pronounced febrile temperature.

As elimination is the basis of the treatment of all such cases, it is clear that this current furnishes an admirable means to bring about this result, and it is therefore also very useful in colds, bronchitis, and respiratory difficulties. We read here and there of what to take to abort a cold. I would suggest

some autocondensation treatment, followed up by some aspirin, quinine, and a hot lemonade. It is effectual beyond all peradventure.

Asthma, being a reflex neurosis, depending upon some irritating point in the system, as nasal, bronchial, gastric, intestinal, or secondary to some systemic disease, and caused by the contraction of the smaller bronchi, yields readily to the high frequency current, which, being antispasmodic in its action, readily dilates the constricting vessels and in a short time produces a great improvement and often a lasting cure. Here we find often the autocondensation sufficient, though in severe cases I would advise the diathermic treatment. As I lack as yet a sufficient personal experience to speak categorically upon the absolute value of this current in cases of pulmonary tuberculosis, I prefer to send such patients to the mountains, in combination with the high frequency treatment to be used there. I would advise, however, in cases where there is a pulmonary weakness without there being any tubercle bacilli found in the sputum, a systematic prolonged high diathermic treatment, which would materially strengthen the lungs and possibly prevent an entrance of the tubercle bacilli into the tissues.

The current by its effect upon the circulation relieves congestion of the tissues and prevents inflammatory conditions which arise from this engorgement. It is, therefore, effectual in all catarrhal conditions, as can be seen in the following case:

CASE XIII.—Miss L. B., 32 years old, had been suffering for many years from frequent attacks of pain in the gall-bladder, the pain shooting up toward the right shoulder, pathognomonic of gallstones. While I advocate operation in such cases, the patient was in such a debilitated condition that I was persuaded to use the high frequency treatment before employing radical measures. The treatment extended through many months, and though there was never any physical evidence of stones having passed, she improved greatly in her condition and has hardly any pains now.

We know that gallstones *per se* do not cause any pain, but are only painful when we have an inflammation of the mucous membrane of the gall-bladder. The current, therefore, evidently restored this part to a normal condition and removed hereby the cause of pain.

In appendicitis I have followed the invariable rule that unless there was an improvement of the patient in twenty-four hours the case was of an operative nature; though we know that usually the first attack is followed by others and that operation is finally necessary. Considering, however, that many of these cases are purely catarrhal without being primarily of an infectious nature, I have in the last five years used this treatment after the cessation of the acute attack and have on record four cases of one attack, and one case of two attacks (this one I saw only in his second attack), where there has been no other attack within the period of one to five years. Of course, I know that this fact does not bar the possibility of their falling victims to this disease again, but meanwhile they are entitled to a suspension of judgment.

In this connection I wish to cite two surgical cases:

CASE XIV.—Miss G. V., 32 years old, in descending from a car fell into a cavity of the street which was torn open on account of a subway construction. The injury to her right knee was so extensive that in spite of her absolute rest for 3 weeks, combined with appropriate treatment, it was determined to send her to a hospital for surgical intervention. Before invoking this measure, however, the patient was brought to

me for a further examination. An x-ray picture showed no injury to the bone but a marked infiltration of the soft tissues, making it impossible for the patient to use the foot to any degree. Daily diathermic treatment followed by the glass vacuum application brought the case to a successful termination in about 6 weeks and enabled the patient to use her foot as well as ever.

CASE XV.—Miss L. R., 30 years old, in falling from a bicycle broke the lower end of the tibia, and after two unsuccessful settings of the limb, 6 weeks having meanwhile passed, had to be operated upon. With the aid of Lane's plate a perfect union resulted. However, in spite of this apparent bony success, the patient could not use the limb, a rather severe infiltration of the soft tissues having followed the early operation and still being present. A course of the same treatment as in the preceding case was entirely successful in restoring the natural contour of the foot as well as its functions.

The potential qualities of the high frequency current in subduing inflammatory conditions, in restoring stiff joints to their original flexibility and usefulness, have been fully recognized by the medical authorities of the warring nations, for it is used in almost all the field hospitals where the crippled and rheumatic soldiers exposed to the climatic changes in the trenches, are taken care of.

While the high frequency current has shown a curative effect in all those preceding illustrative cases, I shall now discuss three groups of diseases where the current may bring about a cure in the early stages, but will so greatly modify the worst manifestations of the chronic condition and contribute so much to the well-being of the patient that I consider its use in these diseases almost imperative. I shall not enter into details about the different types of kidney diseases, for after all they have all the same pathological basis, an inflammation and subsequent degeneration of the kidney tissue. While I invoke all the therapeutical measures in these cases, as medicine, diet, hygiene, and hydrotherapy, I have more faith in the efficiency of this current than in all the other therapeutic means. In its diathermic application it relieves the congestion and regulates the vascular supply of the kidneys, and by aiding their efficiency of elimination prevents in most instances a further degeneration and practically keeps the disease in *statu quo*, thereby materially increasing the chances of a prolongation of life. As it is my conviction that diabetes is primarily a nervous disease, affecting profoundly the metabolism of the body and filling the blood with an excess of sugar, it is self-evident, therefore, that the high frequency current is an extremely valuable remedy in these cases. While the dietary regimen is an absolutely essential feature in the treatment of this disease, the autocondensation application will materially aid in the diminution of the sugar percentage as well as in both improving the nervous system and aiding the metabolism of the patient.

But it is in arteriosclerosis that we find the high frequency current the remedy par excellence. I have had a great many cases of this nature and I can absolutely affirm that every patient has left me on the completion of the treatment with the assurance and the evident appearance that he had been greatly benefited by the current, and that all those little reminders of old age's insidious approach had either entirely disappeared or had greatly lessened. It is rare that the physician is consulted in the very beginning of the disease, as its early manifestations, as a little dizziness, tingling in the extremities, that tired feeling which at times takes possession of so many of us are not sufficient to arouse any suspicion of the nature of the trouble; but when

the patient complains of a great deal of palpitation or of precordial tightness on exertion, when rapid walking becomes an impossibility, when every little exertion becomes almost painful, then the physician's advice is fervently sought and every aid and relief appreciated. As in all chronic diseases, diet, hygiene, moderate living free from excitement and strenuousness are necessary elements in the management of the case, to which we add the life-giving qualities of this current. With an amelioration of the general condition, there is generally a fall of the blood pressure, an evidence of the lessened obstruction to the blood current. When we consider the constant effects of this current upon circulation, upon metabolism, upon excretion, we can hardly wonder at the result it produces upon a system which needs help so badly. I would compare it with that timely lift which one so gratefully appreciates when wearied from climbing a hilly path—a gentle arm aids one in the final ascent.

It is, therefore, not an exotic dream but within the domain of a stern reality to believe that this current, so potent in arresting the disintegrating progress of life's *bête noire*, hardening of the arteries, can be used successfully to prevent or, at least, to postpone the epoch of its arrival. I am satisfied that by its regular and timely application this current would perhaps not perpetuate eternal youth, but would vindicate the accepted maxim that man is as old as his arteries, by preventing their early aging.

The following case represents fully the general type of the disease in not too advanced a stage and will serve sufficiently in showing the benefits from this treatment:

CASE XVI.—Mr. E. H., 68 years old, has been suffering greatly from precordial pains on the slightest exertion. He is hardly able to walk a few blocks without experiencing pain, is easily fatigued, and his digestion is poor. An examination shows a cardiac hypertrophy with an accentuation of the aortic second sound, a hard, tense pulse and a blood pressure of 180. A course of twenty-five autocondensation treatments, given three times a week, brought the blood pressure down to 165—the degree of the improvement on this point varies in many cases—improved his digestion, and made it possible for him to walk for quite a distance without any pain whatever. His general condition was infinitely better and remained so for about eight months, when he took a second series of treatments. It is always necessary to repeat these treatments within six to twelve months, as the effect wears off during this time.

We now approach another phase of old age's discomforts and inconveniences, an enlarged prostate with its tribulations of frequent urination. We know that surgery is often successfully resorted to, but unless the case is extremely bothersome we prefer to suffer rather than to risk an operation at an advanced age. However, while the high frequency current cannot entirely abolish the ravages of age, it can undoubtedly improve the condition sufficiently to warrant its use in every case before submitting the patient to surgical measures. Though I have had fair results with the rectal glass electrode, I have in the last years used the diathermic method with the most gratifying results. While in some cases the diminution of the gland is not a very pronounced one, nevertheless the frequency of urination has been greatly lessened. The following case is a typical one and shows clearly the improvement following a prolonged diathermic treatment:

CASE XVII.—Mr. M. A., 72 years old, consulted me in regard to his frequent urination, being under the con-

stant necessity of emptying his bladder almost every hour during the day and night. On rectal examination I found a rather large prostate, undoubtedly causing this symptom. He had a diathermic application three times a week for about three months with the result of diminishing both the area of his enlarged prostate and the frequency of his urination. He was able to hold his urine for three hours at the time, and never was compelled to void it during the night more than two or three times.

I have also used this current in acute and chronic prostatitis by the diathermic method and am absolutely convinced that its use in all such cases will bring better and quicker results than any other mode of treatment bereft of this effective auxiliary measure.

As stated before, the current is a powerful antiseptic agent, and, therefore, extremely useful in all cases of boils, carbuncles and infected wounds, as well as in inflammations of the lymphatic glands. In the early stage of the inflammation before supuration has taken place, its action is both absorbing and germ destroying; and it hastens the terminal stage after the pus has been evacuated and thoroughly drained. The following interesting case speaks with its own eloquence:

CASE XVIII.—Mr. E. K., 25 years old, consulted me in regard to a chain of about six carbuncles encircling with a rather grim tenderness his unwilling neck. He had been suffering for a year from these decorative endearments, and though they had been cut and poulticed and had been subjected to all sorts of vaccine treatment, together with medicinal measures, they were loth to part company with my client. After opening two of these carbuncles filled with pus, I applied the glass electrode to all of them and persisted in its use daily in the beginning, and then every other day for about six weeks. The persuasive power of the current was too much for them, they departed in peace, and though two years have since gone by, they are still counted among the absentees.

I have had also several cases of cervical adenitis, in which a disappearance of these enlarged glands followed promptly the application of this current. Though I could relate a few more interesting cases which have been successfully treated by this current, it would be but a repetition of the success shown in others and would transgress the limits of this short essay. I shall, therefore, but briefly touch upon the fulguration treatment for which this current can be used in cases of hemorrhoids, carbuncles, warts, moles, and other skin blemishes. Of course, a general practitioner is not apt to get many such cases, nevertheless it is gratifying to state that all the cases I have treated have been markedly successful. I shall quote the following case of internal hemorrhoids:

CASE XIX.—Mr. F. S., 62 years old, was operated upon for bleeding internal hemorrhoids several years ago, and remained well up to a few months before consulting me. On examination I found a group of small bleeding hemorrhoids not far from the sphincter and very accessible. After thoroughly cocainizing them, I employed fulguration for about 10 minutes twice a week. Three weeks sufficed practically to efface them—the bleeding was controlled after two treatments—and though three years have elapsed, no return has taken place.

Unless the hemorrhoids are very large and numerous, in which case an operation is the only remedy, the fulguration method is extremely satisfactory. It is practically painless, does not interfere with the work of the patient, and is absolutely efficient in its results.

In view of the many brilliant results the high-frequency current produces, it may be astonishing to many that it is not as much employed as its

merits deserve. The answer is a simple one: it requires a great deal of time on the part of both patient and physician—time of application as well as duration of treatment—involving an expense which is beyond the means of many who really are in need of this treatment. It is, therefore, not used as much as it should be in acute cases, and employed only as the last refuge in chronic cases when other means have failed to serve the purpose.

While I do not wish this current considered a panacea, still there is no other remedial agent comparable to it in its wide application and curative potency—a veritable elixir of life.

THE USE OF STEAM IN THE TREATMENT OF SUPERFICIAL CANCER.

By WILLIAM J. GILLETTE, M.D.,

TOLEDO, OHIO.

SURGEON TO ROBINWOOD HOSPITAL.

THE value of heat in the treatment of cancer is now pretty generally conceded. As is well known, John Byrne was one of the first to recognize its possibilities, and, employing it for cancer of the uterus, had surprisingly good results.

Dr. Fredericks of Buffalo followed in his footsteps and had likewise excellent results in the same class of cases. These gentlemen used heat of sufficient intensity to cauterize the tissues, which we know is not necessary. Haaland found that the cancer cell is destroyed at a temperature between 122° and 136°, a temperature that does not destroy the normal structure. With this idea in mind, the past few years Dr. J. F. Percy of Galesburg, Ill., has been able greatly to advance the treatment of cancer of the uterus with his especially devised heating irons (not cautery irons) and water cooled specula. His operation is in no sense a cauterizing operation and does not undertake the removal of any portion of the uterus.

The marked success obtained by this method, even in cases otherwise inoperable, not only by Dr. Percy, but others who entirely confirm his claims, together with my own previous experience with the cautery, led me to employ heat also in the treatment of superficial cancers. For this purpose, the past two years, I have used superheated steam, and have found it of great value in the destruction of large fungating cancer and sarcoma masses and in subjecting large surfaces to heat as after the removal of the mammary gland by the Halsted operation. I have used it seventeen times upon sixteen cases and have been greatly pleased to see under its influence cancer masses promptly disappear with satisfactory healing. So far as I know, in four instances only has there been recurrence and in one of these I have had the privilege of resteamng with apparently good prospects of ultimate cure.

Of course it is yet too early to say others of this series will not recur. If recurrence does not take place locally, it is too much to expect that in all, metastasis had not taken place before operation, and in such, recurrence is sure to follow. All of these patients, with the exceptions noted and three now undergoing treatment, are clinically well. The tremendous influence of steam in the destruction of cancer is so marked and satisfactory that I am sure in time it must become a recognized agent in the treatment of cases suitable to its employment.

So far as I know, it has never heretofore been used in the treatment of cancer, though Doyen a few years since is reported to have experimented with steam as well as hot air and hot water, but discarded them all in favor of the high frequency current (diathermy). I believe he did not actually employ steam for the treatment of cancer, thinking that it would not sufficiently penetrate tissue. This conclusion was certainly incorrect, for under proper pressure, it may be made to penetrate tissues to the depth of an inch or more. It does not readily permeate fascia or firm layers of fat, but this objection is easily overcome by puncturing with the scalpel, in multiple places, any fascia over which it is to be applied or, what is better, by removing it entirely. The same procedure may be employed with fat.

Again, steam has a selective property in most cancer cases, for the reason that it follows the line of least resistance, and cancer usually being not of so firm a texture as its surrounding tissues, will be in-

vaded when the neighboring structure is left intact. This I consider one of its most valuable characteristics. To my surprise, following its use, I found that patients were entirely free from pain and usually remained so throughout the entire process of healing.

For the employment of steam, I have had DeVilbiss & Co. of this city, make me some metal shells, as shown in the cuts, enclosing tubes of small diameter through which steam is forced into cancer tissues, at a boiler pressure of from fifty to fifty-five pounds. The shells act as a protection to structures it is not desired to treat. They are made in four sizes and used attached by a handle to a six-foot length of fiber-tubing able to withstand a pressure of one hundred and twenty pounds.

The used steam is carried from the shell by way of the small nipple, at its upper end, to which is attached a rubber tubing leading to a pail of water. This instrument, while crude, and leaving many improvements to be desired, is yet efficient, and I have employed it with a very high degree of satisfaction.

A PRACTICAL METHOD FOR ESTIMATING THE PROTEIN CONTENT OF CEREBRO-SPINAL FLUID.

By J. A. F. PFEIFFER, M.D.,

WASHINGTON, D. C.

CONSIDERABLE importance has been attached to the results of investigations regarding the protein content of the cerebrospinal fluid, which have been utilized in recent years by neurologists and psychiatrists throughout the world, for the differential diagnosis between syphilitic diseases and other affections of the central nervous system.

The amount of protein contained in normal cerebrospinal fluid is quite small, and consists chiefly of globulin and albumose. In acute and chronic inflammatory conditions of the nervous system, an increase of the protein content of the fluid occurs, usually associated with a marked leucocytosis. In cases of progressive degeneration, irrespective of the great excess of fluid, it is found that proteins are greatly increased in amount. A considerable part of the proteins may be coagulated by heat between 75° and 80° C.

The various methods which have been devised for the determination of proteins in different fluids, after some modification, are in most instances also applicable to the cerebrospinal fluid. A number of different reagents have been employed both in the qualitative and quantitative estimation of proteins, such as alcohol, ammonium sulphate, butyric acid, sulphosalicylic acid, and others. Ammonium sulphate has been used by Nissl for the demonstration of globulin in the cerebrospinal fluid, and by Nonne and Apelt in performing their reaction.

Sulphosalicylic acid has been shown to be an excellent precipitant for quantitative work, and has been utilized in this laboratory for some time in the routine examination of the cerebrospinal fluid for protein in the following manner, which has proven to be a most convenient, practical and satisfactory method: 3 c.c. of a 4 per cent. solution of sulphosalicylic acid are placed in a test tube 1 cm. in diameter, and 0.5 c.c. of cerebrospinal fluid allowed to flow down the side of the tube on to the surface of the acid, when a characteristic white ring appears, if an excess of protein be present, which reaches its greatest intensity in two minutes. An approximate estimation as to the degree of excess may be obtained by performing the test in several tubes, with dilutions of the spinal fluid from one to five, and comparing the results.

Dementia Precox and the Adrenal Gland.—Dunlop Robertson states his belief that the catatonic type of dementia precox is due to an excess of adrenal secretion in the blood. He has come to this belief through a mass of testimony in the literature and through the result of a blood test made by himself. Two samples of blood were taken—one from a normal person, the other from a catatonic, and tested with a solution of potassium bichromate. The addition caused a quite dark coloration of the catatonic blood, the other blood presenting no change. In anticipation of the objection that the adrenal secretion should cause increased blood pressure, whereas in catatonic precox the blood pressure is usually lowered, the author suggests that it is not improbable that an excess of adrenalin may reduce the pressure, for it is well known that many organic substances produce opposite effects according as they are given in large or small doses.—*Journal of Mental Science.*

MEDICAL RECORD.

New York, January 8, 1916.

NATIONAL QUARANTINE.

IT is very probable that the cessation of the war in Europe will be shortly followed by a vast emigration from all the now warring countries to the United States. The possible shortage of labor in those countries will be more than balanced by the business depression and poverty that will prevail, and the contrast of the material prosperity of this country will attract men and women of all classes as it never did before. With these hordes of seekers for peace and plenty will come to us the danger of infection, and the responsibility of the quarantine authorities in all ports of the Atlantic coast will be immeasurably increased. A consideration of this possibility, or rather probability, must keep acute the question of national control of the quarantine stations of the country.

As the MEDICAL RECORD has repeatedly urged, the prevention of the introduction of disease into the United States is preeminently a function of the general government and not one of individual States or municipalities. Since most of the immigrants who enter through any port, especially that of New York, do not remain there but scatter to every State in the Union, the problems associated with immigration are necessarily national ones. This fact is recognized fully and acted upon in all respects save in the matter of quarantine, and even in the latter with the exception of the two ports of Baltimore and New York, all the other quarantine stations of the country being now in charge of the United States Public Health Service.

There is absolutely no reason why New York should not follow the example of the sixty-seven ports which since 1888 have transferred their quarantine functions to national control, and the recent regrettable death of Dr. O'Connell, the health officer of this port, would seem to emphasize the wisdom of making the transfer at this time. If the Public Health Service is invited to take control now the station will be at once placed in charge of experienced officers, whereas if a new State official is appointed, although he may eventually become as efficient as was Dr. O'Connell, he will have first to acquire experience, and in the meanwhile New York and the entire nation may have to suffer from the consequences of mistakes which even an expert sanitarian is liable to make while familiarizing himself

with the difficult conditions of the New York quarantine service. Such an opportunity to make this change without the necessity of displacing a faithful officer is unique, deplorable as is the event which has brought it about, and Governor Whitman has shown that he is alive to the situation by recommending, in his annual message to the Legislature, that the office of Health Officer of the Port be abolished.

THE CONTROL OF TUBERCULOSIS.

TUBERCULOSIS is an infectious disease, presumably acquired by the inhalation or ingestion of the specific bacilli extruded from the bodies of tuberculous men or animals. It is possible therefore that the strict isolation of all sick humans and the slaughter of all sick animals continued over a long period would bring about the extinction of the disease. This is, of course, assuming that the parasite cannot live and multiply for any considerable period in other media than animal tissues, and that other acid-fast or non acid-fast organisms cannot, through a process of mutation, acquire the pathogenic properties of Koch's bacillus.

One is encouraged to believe in the possibility of the extinction of this disease by the results obtained by isolation and early treatment of the tuberculous. At the recent Second Annual North Atlantic and New York State Conference on Tuberculosis, Dr. Victor G. Heiser, Director for the East of the International Health Commission, Rockefeller Foundation, stated that in Victoria, Australia, tuberculosis had been virtually stamped out by the simple method of prompt treatment of every individual afflicted with the disease. This treatment is carried out in the man's home if the authorities have convinced themselves that he does not constitute a center of infection there and has a reasonable chance of becoming cured; but if the sanitary officers, after investigation, are convinced that the patient cannot be treated safely at home, he is removed to an institution. If the patient is the bread-winner of the family and has no means and his invalidity insurance is insufficient, the municipality assumes the responsibility of taking care of the family until the bread-winner is restored to his earning capacity. Women and children, when tuberculous, are taken care of in the same way as the adult males, that is to say, they are removed from their homes, when in the opinion of the sanitary authorities they constitute a menace to their families or the community, and are subjected to enforced segregation in a sanatorium or hospital.

It is difficult to conceive of the carrying out of any such plan as this, at least in its entirety, in any of our large American cities, as for example New York or Chicago, with their heterogeneous populations and their social conditions and economic laws so different from those in Australia. With conditions as they exist here to-day the enforced segregation of the tuberculous would often work extreme cruelty such as would not be tolerated by public opinion. The authority to do so undoubtedly resides in our boards of health, but no health officer would dare, even if he had the will, to exercise such authority until the public had been educated up or

down to the idea that the community, the State, is everything, the individual nothing, or until phthisiophobia had so obsessed the public as to drive it to the same extreme of hysterical inhumanity as leprophobia, for instance, does to-day.

Dr. Heiser, however, is rather more optimistic, for he believes that "by a united effort on the part of the statesmen, to bring about insurance against disease, including tuberculosis, on the part of the municipal authorities, enforcing antituberculosis laws and regulations as above outlined in a strict but humane way, and lastly, on the part of philanthropists aiding both agencies by improving general housing and working conditions of the masses, the tuberculosis problem might be solved in the United States as well as it has been solved in Australia, in less time than is thought possible. It needs a wise and just government, a practical and expedient municipality, well trained sanitarians and physicians, and an intelligent people and the goal can be reached." These, we must admit, are rather large needs; but, no doubt, if we had such a government and such a people, such wise statesmen and more of such philanthropists, this and every good and desirable sanitary goal could be reached with ease and certainty.

THE ESTIMATION OF TOLERANCE TO SUGAR.

It has been the custom to estimate a patient's tolerance to sugar by determining how many grams of the substance can be given by mouth at one time without causing glycosuria. The objections to this method are quite obvious for the degree of increase in the blood sugar, following such a dose must depend upon the amount of the total dose absorbed from the stomach and the rate at which it is absorbed as well as the rate at which the body cells are able to utilize this material and the amount which can be contained in the storage places in the body. It is clear then that in order to determine the ability of the body to utilize sugar, the substance must be administered directly into a vein and the result expressed in terms of time as well as rate, *i.e.* grams of glucose per kilo of body weight per hour of time.

This argument is clearly set forth by Woodyatt, Sansum, and Wilder (*Jour. Am. Med. Assn.*, 1915, lxx, 2067), who have devised an apparatus whereby solutions can be driven into a vein at a regular and fixed rate. As a result of their experiments they have found that a normal rabbit, dog, or man can utilize between 0.8 and 0.9 gram of glucose per kilo of body weight per hour without glycosuria for an indefinite time. Injections have been given for as long as two and one-half hours to man and twelve hours to animals. They emphasize the possibility of using the method for feeding, for at the above rate a man may receive 252 calories per hour into the vein and be able to utilize them. The tolerance for other sugars, levulose, galactose, and lactose, was found to be much lower than the figures given above. If now the amount of sugar administered be increased above the tolerance limit, a glycosuria is induced and with it

a polyuria. When the rate reaches 5.4 grams per kilo an hour about 3.6 grams per kilo an hour are excreted in the urine and the diuresis is enormous. The amount of urine has reached the almost incredible figure of 600 c.c. per 10 kg. of body weight for one hour which would correspond to 100 liters in the twenty-four hours for a man weighing 70 kg. Needless to say, such a process cannot last long, for if no water is supplied the animal soon becomes dehydrated, while if enough is supplied to make up the deficiency the heart soon gives out.

The clinical applications of these observations are obvious, and the authors mention a number of them. The intravenous administration of food; the abstraction of any desired amount of water from the body; the flushing of the body with a great stream of water in the case of poisoning; the application of the method to diabetic coma, uremia, edema, bichloride poisoning, etc., are naturally thought of at once. Whether it would be advisable to attempt it on man is at least debatable. One should have experience with the possibilities in animals before beginning to use it therapeutically. These authors state that such work is being done in their laboratory and we shall await with interest the results of their observations. Those already published are of very great interest and seem to promise much.

NANISM.

It was inevitable that nanism, no less than gigantism, should be attributed to some disorder of the endocrine glands, although considerable time has been required to furnish the proof. This is true not only of dwarfism from under-development of certain parts of the skeleton, but also of the essential form. At a session last summer of the Hamburg Medical Society (*Deutsche medizinische Wochenschrift*, September 23) Konne reported two cases of dwarfism of the so-called Lilliputian or symmetrical type. One female, aged 18, represented both somatic and psychic infantilism. Growth began to show arrest in the third year. The mental processes were those of a child of seven. There were no apparent disorders of the thyroids, parathyroids, adrenals, or pineal body. The sella turcica was normal in the x-ray picture. Two facts, however, pointed to the hypophysis, viz., glycosuria and a positive Abderhalden reaction (breaking down of hypophysis substance in the blood). The girl had never developed sexually. The other patient, male, was a Lilliputian up to the age of 30, of the infantile type. After this period his lower extremities began to grow slowly. The sella turcica was markedly expanded. After his death from phthisis a teratoma of the hypophysis was discovered. The testicles were those of a newly born child.

TETRAGENUS MENINGITIS.

ALTHOUGH the *Micrococcus tetragenus* is regarded as generally non-pathogenic in man, excepting as an associated pyogenic organism in tuberculous cavities, in acute abscesses, and in the pus of empyema, nevertheless it may sometimes play a definite pathogenic rôle of its own. Lenglet and Sacquépée have recently observed among French soldiers a small

epidemic of a disease characterized by the presence of a continued fever resembling that of typhoid fever, but with pulmonary, digestive, and vasomotor complications that gave it a distinctive character. Examination of the blood in these cases revealed the tetragenus in association with a diplococcus as yet unknown. The prognostic outlook was generally favorable. With these cases there may be classed the two cases of tetragenus meningitis also observed among French soldiers and reported by Felix Ramond and André Résibois in *Le Progrès Médical*, September, 1915. Both of these cases began like typical cases of cerebrospinal meningitis. Symptoms of gastroenteric disturbance were quite pronounced. In one of the cases there were a marked bronchitis and cyanosis of the extremities. The *Micrococcus tetragenus* was isolated from the fluid obtained by lumbar puncture. Recovery ensued in both instances.

PROTECTIVE FERMENTS IN LEUCEMIA.

THE Abderhalden reaction has been interpreted as the expression of the process by means of which the blood destroys foreign protein introduced into it from outside the body, or protein derived from any of the tissues or organs of the body, but not ordinarily circulating in the blood. In pathological conditions of these tissues or organs a certain amount of disintegration occurs, as the result of which protein alien to the blood enters this fluid and excites the formation of a destructive ferment. Grazia Norzi (*Pathologica*, September 1, 1915), has found definite evidences of this sequence in cases of leucemia. Applying the method of Abderhalden he tested the blood serum of six patients with the aid of extracts of various organs involved in leucemia, and in four instances he obtained positive results. The conclusion is reached that in leucemia the organism elaborates ferments that digest the protein set free from the bone-marrow, spleen, and lymph glands. These ferments have no effect upon the protein of the normal organs, but are not absolutely specific, for in two cases they have been found to exert their digestive action upon placental tissue.

News of the Week.

Stamping Patent Medicines.—Three hundred inspectors, recruited from the sanitary, medical, and food bureaus and from among the visiting nurses of the Department of Health, New York, were assigned on December 27 to the task of stamping approximately 5,000,000 packages and bottles of patent medicines in the retail drug stores of the city. The stamping was necessary in order to distinguish the packages already in the shops from those added to the stock after January 1, when the registration law for such preparations becomes effective. The new law requires that the ingredients of all patent medicines shall be printed on the wrappers, or that the Health Department shall be furnished with the formulæ for their preparation for its files. The law, of course, does not apply to medicines already in stock in the retail stores.

Plan to Reorganize All City Hospitals.—Commissioner Kingsbury of the Department of Charities, New York City, has under consideration the reorganization of all the city hospitals under his control, and as his plans have already been approved by the trustees of Bellevue and allied hos-

pitals they will probably be put into effect in those institutions as soon as the necessary amendment to the present law is passed by the Legislature. The reorganization has already been begun at the Cumberland Street Hospital, Brooklyn, with a request for the resignations of the fifty-seven physicians on the staff, and this has met with a protest from the affected physicians, who believe that an attempt is being made to put the hospital service into politics. As so far announced, the Commissioner's plans include the substitution of a small salaried medical staff with a continuous service for the large medical staff with a rotating service. The chief of each division in the hospital would employ his own assistants, who would be paid for constant attendance at the hospital, thus, in the Commissioner's opinion, improving the hospital service. In the opinion of the protesting physicians, however, this centralization is a step backward, puts the hospital into politics, wastes the public funds, is unfair to the young physician, and will lead to demoralization and poor service.

Death Rate High.—The noteworthy feature of the mortality report for the week ending December 25 in New York City was the increase in the number of deaths due to pneumonia and influenza. The deaths due to the latter disease were 24 or nearly five times as many as during the same week of last year, while those due to pneumonia were increased by nearly 200 as compared with 1914, lobar pneumonia causing 251 and bronchopneumonia 117. The mortality from pneumonia being estimated at 20 per cent., it may be assumed that during the week there were nearly 2,000 cases of the disease in the city. Similar reports of epidemic pneumonia and influenza have been received from other cities, and the New York Department of Health has renewed its warning to keep away from those who are coughing or sneezing and out of crowds as much as possible. The total number of deaths from all causes reported during the week was 1,724, as compared with 1,363 during the corresponding week of last year, the respective rates being 15.49 and 12.74. The death rate for the fifty-two weeks was estimated at 13.55, as compared with 13.60 for last year.

Grand Prize to Health Department.—Announcement has just been made of the award by the Jury of Awards of the Panama-Pacific Exposition of a Grand Prize to the Department of Health of New York City for its work in health and sanitation. While a number of prizes were awarded to the city, the Department of Health was the only individual department to receive a Grand Prize.

Duhring Memorial.—On December 13, the trustees of the University of Pennsylvania formally dedicated the Duhring Memorial Building, forming a new wing to the University Library. This has been erected in memory of Dr. Louis A. Duhring, late professor of dermatology in the medical school of the University, who bequeathed to the University his estate of over a million dollars.

Æsculapius for Terpsichore.—Nijinski, the Russian dancer, is a prisoner of war in Austria; Dr. Robert Bárány, the Viennese aurist and winner of the Nobel prize in medicine, is a prisoner in Russia. Mr. Burian, the Austrian premier, has suggested through a neutral ambassador that the two prisoners be released, each to return to his own country to follow henceforth the arts of peace. He apparently regards it as a fair exchange.

Hospital Under Fire.—An official statement

issued at Berlin on December 29, states: "Our artillery bombarded the railway station at Soissons, where the French recently had provided a hospital in the immediate neighborhood of the railway station with a Red Cross flag. On account of its proximity to the station it was not possible to exclude the possibility of hitting the hospital."

The American Ambulance.—Ex-Ambassador Bacon, who went to France two months ago to inspect the work of the American Ambulance, returned to New York on December 28. He reports that the cost of running the institution was \$1,000 a day, which was much less than in the beginning, and that there are now 610 patients in the hospital at Neuilly and 500 others in beds hired outside.

Dr. David F. Wheeler of Buffalo, N. Y., who enlisted in the Foreign Legion of the French Army last spring, received on Christmas Day the decoration of the War Cross. Dr. Wheeler was wounded on September 28, and is spending the time of his convalescence in working for the American Ambulance.

Gift of Hospital Train.—Two Americans, it is announced, have furnished money for the equipment and maintenance of a hospital train, with a capacity for 240 wounded men, to be operated in connection with the American Ambulance at Neuilly. The train will run from designated points behind the front to Paris or other hospital centers, and will consist of an operating room, a pharmacy, a kitchen, etc.

Need in Serbia.—It is reported that several members of the American Sanitary Commission who left Serbia in November, have been recalled to Saloniki to take up general relief work. Conditions in that country are said to be very serious, the food supply being short because of the seizure of foodstuffs collected by the American workers.

Murders in 1914.—In a recent compilation of records of homicides in American cities during 1914, Mr. Frederick L. Hoffman gives the total number of murders in the United States during that year as 8,000, of whom 80 per cent. were men. Memphis, Tenn., had the highest number murder rate, 72.2 per 100,000 of population; while Reading, Pa., had the lowest, 1 per 100,000; New York had a rate of 6.1, and Chicago a rate of 9.1 per 100,000. The eight cities having the highest rates are all in the South. In Philadelphia the rate was only 4.6, and in Boston 3.4. The total number of murders in New York City was 280, and in Chicago, 217. During the decade 1904-13 the average murder rate for all cities was 7.9 per 100,000, while in 1914 the rate was 8.6, an increase of nearly 9 per cent. During the same time the suicide rate increased only 3.6 per cent. Sixty per cent. of the murders were done with firearms, 15.1 per cent. with cutting or piercing instruments, and most of the victims were between the ages of 25 and 34.

Object to "Twilight Sleep Home."—Some of the residents of Riverside Drive, New York, in the neighborhood of Seventy-second Street, are aroused over the opening on the Drive of a hospital for the administration of "twilight sleep," and have applied to the courts for an injunction, claiming that the use of the property as a hospital violates the restrictive clause in the deed covering all the land in that vicinity. The property in question was leased last July for a term of five years, and has since been used as a private sanatorium where "twilight sleep" treatment is given. The plaintiffs claim

that by virtue of such occupancy the premises threaten to become notorious as the New York Home for Twilight Sleep, and that such use and occupancy are an invasion of their privacy and rights.

Dies at 102.—Mrs. J. B. Stock of Duluth, Minn., who was born in County Kerry, Ireland, in 1813, died at her home on December 30, leaving 4 children, 20 grandchildren, 20 great grandchildren, and several great-great-grandchildren.

Misuse of Red Cross.—Complaint has been made to the Attorney General of the United States that a number of physicians of Saginaw, Mich., are violating the law prohibiting the use of the Red Cross emblem by having it emblazoned on their automobiles. An inquiry into the charges will be made.

The Herter Lectures.—The University and Bellevue Hospital Medical College announces that a course of five lectures, under its Herter Foundation, will be given by Prof. Victor C. Vaughan of the University of Michigan on "Poisonous Proteins." The first lecture will be delivered on Monday, January 10, at 4 P. M., at the Carnegie Laboratory, 336 East Twenty-sixth street, and the others will follow daily at the same hour.

Bronx County Medical Society.—At the regular meeting of this society, to be held at Ebling's Casino, 156th street and St. Ann's avenue, on Wednesday of next week, the paper of the evening will be by Dr. Charles H. Mayo of Rochester, Minn., on "Gall-Bladder Disease." The subject will be discussed by Drs. Charles H. Peck, Charles A. Elsberg, John F. Erdmann, Franz Torek, John Rogers, Irving S. Haines, William P. Healy, Benjamin T. Tilton, and others.

Charitable Bequests.—By the will of the late Charles S. McKelvey, chief engineer for the New Jersey Board of Public Utilities, who died in Paterson on December 16, the Paterson General Hospital and St. Joseph's Hospital, Paterson, receive bequests of \$13,000 each.

The Brooklyn Eye and Ear Hospital receives \$5,000 and the Brooklyn Hospital and the Brooklyn Home for Consumptives \$2,500 each by the will of Col. R. W. Woodward of Brooklyn.

The sum of \$3,000 is bequeathed to the Hospital of the University of Pennsylvania, Philadelphia, by the will of the late Helen F. Knight of Lower Merion, Pa., for the endowment of a free bed in the children's ward in memory of Mrs. G. Lee Knight.

By the will of the late Bernard Harburger of Philadelphia bequests are made as follows: Jewish Hospital Association of Philadelphia \$500; Mt. Sinai Hospital, \$500; Philadelphia Jewish Sanatorium for Consumptives, \$500.

Personals.—Dr. STEWART HAMILTON has been appointed superintendent of the Harper Hospital, Detroit, Mich., to fill the vacancy caused by the death of Dr. Wayne Smith. Dr. Hamilton was formerly assistant superintendent and physician in charge of the institution.

Dr. FREDERICK P. GAY, professor of pathology in the University of California, has been selected as faculty research lecturer for 1916, in recognition of his work in immunity in pneumonia and typhoid fever. On the University Charter Day, March 23, 1916, Professor Gay will deliver the annual public address on the results of his research in some special field.

Dr. WILLIAM F. MATTHEWS, deputy health officer of the Port of New York, was designated acting head of the service by Governor Whitman on Janu-

ary 1, pending the appointment of a successor to the late Dr. O'Connell.

Medical Society Elections.—LOWNDES COUNTY (GA.) MEDICAL SOCIETY: Annual meeting at Valdosta on December 14. Officers elected: *President*, Dr. DeWitt W. Freeman; *Vice-President*, Dr. James M. Smith; *Secretary-Treasurer*, Dr. Joseph A. Thomas.

SOO LINE SURGICAL ASSOCIATION: Annual meeting at Minneapolis, Minn., on December 9. Officers elected: *President*, Dr. Theodore Bratrud, Warren, Minn.; *Vice-President*, Dr. J. M. Dodson, Chicago; *Secretary-Treasurer*, Dr. J. H. Rishmiller, Minneapolis.

THOMAS COUNTY (GA.) MEDICAL ASSOCIATION: Annual meeting at Thomasville on December 10. Officers elected: *President*, Dr. Lloyd E. Morton, Boston; *Vice-President*, Dr. W. W. Jarrel, Thomasville; *Secretary*, Dr. S. L. Cheshire, Thomasville.

MASSACHUSETTS SURGICAL AND GYNECOLOGICAL ASSOCIATION.—At the 85th annual session in Boston on December 8, the following officers were elected for the ensuing year: *President*, Dr. H. O. Spalding, Westboro; *Vice-President*, Dr. Ralph C. Wiggin, Cambridge; *Secretary*, Dr. Harry C. Lee, Boston; *Treasurer*, Dr. C. Y. Wentworth, Newton Highlands.

SOUTHERN MINNESOTA MEDICAL ASSOCIATION.—The officers were elected at the annual meeting held in Mankato on December 1: *President*, Dr. E. S. Judd, Rochester; *Vice-Presidents*, Dr. J. S. Holbrook, Mankato, and Dr. H. B. Grimes, Madelin; *Secretary*, Dr. W. T. Adams, Elgin; *Treasurer*, Dr. G. F. Merritt, St. Peter.

FALL RIVER (MASS.) MEDICAL SOCIETY: Annual meeting on December 13. Officers elected: *President*, Dr. J. Aladin Barre; *Vice-President*, Dr. Arthur C. Lewis; *Secretary*, Dr. R. W. French; *Treasurer*, Dr. W. S. Lyon.

HARRISON COUNTY (IA.) MEDICAL ASSOCIATION: Annual meeting at Logan on December 8. Officers elected: *President*, Dr. Harry N. Anderson, Woodbine; *Vice-President*, Dr. F. H. Hanson, Magnolia; Dr. A. H. Konigmacher, Missouri Valley.

Obituary Notes.—Dr. CHARLES TOWNSHEND DADE of New York, a graduate of the College of Physicians and Surgeons, New York, in 1891, consulting dermatologist to the Manhattan State Hospital, the Roosevelt Hospital, the Central Islip Hospital, the Englewood Hospital, and the Vassar Brothers' Hospital, Poughkeepsie, chief of the dermatological clinic of the Out-Patient Department of St. Luke's Hospital, and attending dermatologist to the Randall's Island Hospital, and a member of the New York Academy of Medicine, the New York Dermatological Society, and the Society of the Alumni of St. Luke's Hospital, died at his home, after a long illness, on December 26, aged 56 years.

Dr. WILLIAM PHILIP SPRATLING former superintendent of the Craig Colony for Epileptics, Sonyea, N. Y., a graduate of the College of Physicians and Surgeons, Baltimore, in 1886 a former president of the National Association for the Study of Epilepsy, and a member of the American Medico-Psychological Association, died suddenly at Welska, Fla., on December 23, aged 52 years.

Dr. CHARLES F. BURGER of Saint Clair, Mich., died at his home on December 4, aged 84 years.

Dr. EDWARD H. THRAILKILL of Kansas City, Mo., a graduate of the Kansas City Medical College in 1890, associate professor of surgery in the University of Kansas, School of Medicine, and a mem-

ber of the American Medical Association, the Missouri State Medical Association, and the Jackson County Medical Society, died suddenly at his home on December 7.

Dr. WALTER E. SEYMOUR of Riverside, R. I., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1898, and a member of the Rhode Island Medical Society, and the Providence County Medical Society, died at his home on December 7, following an illness of several weeks, aged 41 years.

Dr. LEWIS FREY died at Scranton, Pa., on December 6 at the age of 49 years. He was graduated from Jefferson Medical College in the class of 1888. He was a member of the Lackawanna Medical Society and the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. FRANCIS COFFIN MARTIN of Boston, a graduate of the Harvard University Medical School in 1883, and a member of the Massachusetts Medical Society, and the District Medical Society, died at his home in Roxbury, on December 3, aged 57 years.

Dr. HENRY T. FISHER of Knoxville, Tenn., a graduate of the Lincoln Memorial University, Medical Department, Knoxville, in 1891, died at his home after a long illness, on November 29, aged 67 years.

Dr. JAMES S. MILLER of Mount Pleasant, Tex., a graduate of the University of Louisville, Ky., Medical Department, in 1877, and a member of the State Medical Association of Texas and the Titus County Medical Society, died at his home, after a brief illness, on November 28, aged 63 years.

Dr. MARY HAWES of Denver, Col., a graduate of the Laura Memorial Woman's Medical College, Cincinnati, Ohio, in 1899, formerly staff physician at St. Anthony's Hospital and a member of the American Medical Association, and the Colorado State and Denver City and County Medical Societies, died at her home, after a long illness, on December 8, aged 50 years.

Dr. FRANK H. STUART of Bandette, Mich., a graduate of the Kentucky School of Medicine, Louisville, in 1887, died suddenly at his home on December 7, aged 67 years.

Dr. ERDMANN M. BRANDT of Tarrytown, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1889, and attending physician to the Tarrytown Hospital, died at his home from pneumonia after a short illness, on December 23, aged 48 years.

Dr. ALFRED VICTOR BRAILLY of New York, a graduate of the College of Physicians and Surgeons, New York, in 1875, died at his home on December 22, aged 63 years.

Dr. SAMUEL STILLE of Atlantic City, N. J., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1875, died at his home from pneumonia, on December 23, aged 86 years.

Dr. ROBERT N. WILLSON, JR., died at Philadelphia on January 1 at the age of 43 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1897, after which he became resident physician in the Pennsylvania Hospital. He was for a number of years assistant physician and recently physician to the Philadelphia General Hospital. He was a member of the Philadelphia County Medical Society, and of the Medical Society of the State of Penn-

sylvania and a Fellow of the American Medical Association, a member of the American Association of Pathologists and Bacteriologists and of the Pathological Society of Philadelphia.

Dr. WILLIAM J. ASHENFELTER died at Pottstown, Pa., on January 1 at the age of 66 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1870. He was formerly surgeon to the Sixth Regiment and also of the First Brigade, N. G. P., with the rank of major.

Dr. ARNOLD GUSTAVE LEO of New York, a graduate of the College of Physicians and Surgeons, New York, in 1895, died at his home suddenly, on December 31, aged 43 years.

Obituary.

GEORGE THOMAS JACKSON, M.D.,

NEW YORK.

Dr. GEORGE THOMAS JACKSON, formerly professor of dermatology in the College of Physicians and Surgeons, New York, and consulting dermatologist to the New York Infirmary for Women and Children, died at his home in this city, from pneumonia, on January 3. He was born in New York on December 19, 1852, and after graduating from the College of the City of New York, spent several years in business. In this he received an excellent training, much to his advantage in after life. Preferring a medical career, he entered the College of Physicians and Surgeons, receiving the degree of doctor of medicine in 1878. He served as interne at the City Hospital and then spent two years abroad, studying at the Universities of Vienna, Strassburg, and Berlin. He became professor of dermatology in the Woman's Medical College and Infirmary, New York, in 1890, and in 1897 instructor of dermatology in the College of Physicians and Surgeons, and in 1908 was made professor in the same department, a position which he held with marked ability until his retirement in 1913. He was a member of the American Medical Association, the New York State and County Medical Societies, the American Dermatological Association (at one time president), the New York Dermatological Society (also at one time president), the New York Academy of Medicine, and the Alumni of the City Hospital.

As a contributor to the literature of medicine Dr. Jackson's career was one of more than ordinary importance. He served upon the editorial staff of the *New York Medical Journal* and the *American Medical and Surgical Bulletin* and for several years contributed articles of value upon subjects connected with his specialty. He was also a contributor of dermatological articles to two editions of the "Reference Handbook of the Medical Sciences." His treatise upon "Diseases of the Hair and Scalp" became a standard work, as did his "Ready Reference Handbook of Skin Diseases," now in its eighth edition.

CHARLES C. BARROWS, M.D.

NEW YORK

Dr. CHARLES CLIFFORD BARROWS of New York, professor of clinical surgery in the department of gynecology of the Cornell University Medical College, died at his home after an illness of two

months, on January 2, aged 58 years. Dr. Barrows was graduated from the Medical Department of the University of Virginia in 1879 and from the New York University Medical College in 1880, and after two years' service at Bellevue Hospital entered the medical corps of the United States Army, serving until 1887 in the campaigns against the Indians. Returning to New York, Dr. Barrows became clinical instructor in gynecology in the New York University Medical School and in 1893, on the opening of the Cornell Medical School joined the department of gynecology, in 1913 being placed in full charge. He was a fellow of the American College of Surgeons and the American Medical Association, and a member of the New York State and County Medical Societies, the New York Obstetrical Society, the New York Clinical Society, the New York Academy of Medicine, the Society of the Alumni of Bellevue Hospital, and the Medical Society of Greater New York; and was attending surgeon to the Manhattan Maternity Hospital, attending gynecologist to Bellevue Hospital, and consulting surgeon to the New Rochelle and Peekskill Hospitals.

JOSEPH J. O'CONNELL, M.D.,

NEW YORK.

Dr. JOSEPH J. O'CONNELL, health officer of the Port of New York, died at his home at Quarantine, Rosebank, S. I., on January 1, after a long illness, at the age of 49 years. Dr. O'Connell was born in Brooklyn and was educated at St. Francis' College and in medicine at the Long Island College Hospital, graduating from the latter in 1887. He was for many years sanitary inspector of the Bureau of Contagious Diseases in Brooklyn, and at the time of his appointment as health officer, in 1912, was visiting physician to St. Mary's General Hospital, visiting surgeon to St. Mary's Female Hospital, and alienist to the Kings County Hospital. He was a member of the New York State and Kings County Medical Societies, the American Medical Association, the American Public Health Association, and the Long Island Medical Society, and the author of a number of articles on public health and sanitation. During his term as health officer of the port he effected several changes at Quarantine, the most notable being the construction and equipment of the pathological and bacteriological laboratory, one of the finest in the world. During 1914, when the danger of typhus fever entering the port was very great, Dr. O'Connell perfected a system of disinfection of persons and cargoes entering this port, which prevented the occurrence of a single secondary case of the disease. At the time of his death he was lecturer on hygiene in New York University, lecturer on public health in the Long Island College Hospital, and as health officer a member of the New York City Board of Health.

ISAAC OTT, M.D.,

EASTON, PA.

Dr. ISAAC OTT, former dean of the Medico-Chirurgical College of Philadelphia and professor of physiology in that institution, a distinguished neurologist and author of many medical works, died at his home in Easton, Pa., on January 1, aged 68 years. Dr. Ott was graduated from the University of Pennsylvania, Department of Medicine, in 1869. He was for a time fellow in biology at Johns Hopkins

University, and from 1872 to 1879 lecturer in physiology at the University of Pennsylvania. In 1879 he became lecturer in physiology at the Medico-Chirurgical College, and in 1894 professor. He was a member of the American Medical Association, the Medical Society of the State of Pennsylvania, the Northampton County Medical Society, the Philadelphia Neurological Society, and the American Neurological Society, of which he was at one time president.

DAVID WILLIAM CHEEVER, M.D.,

BOSTON, MASS.

DR. DAVID WILLIAM CHEEVER of Boston, Mass., a graduate of the Harvard University Medical School in 1858, died at his home on December 27, after a short illness, aged 84 years. He was one of the original surgical staff of the Boston City Hospital, which was opened in 1864, a member of the instructing force of the Harvard Medical School continuously since 1861, when he was appointed demonstrator of anatomy, having been made professor of clinical surgery in 1875, professor of surgery in 1882, and professor emeritus in 1893. He was a member of the American Medical Association, the American Surgical Association, which he served as president in 1889, the Massachusetts Medical Society, and the Suffolk District Medical Society, an honorary fellow of the American College of Surgeons, an associate fellow of the College of Physicians of Philadelphia, a foreign member of the Surgical Society of Paris, and the author of several text books on surgery.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BRITISH HOSPITAL SHIPS—GERMAN STATEMENTS DENIED—ORGANIZATION OF PROFESSION FOR WAR SERVICE—R. A. M. C. CALL FOR MEDICAL OFFICERS—USES OF UREA.

LONDON, December 17, 1915.

THE British Admiralty has been constrained to issue a further categorical denial of the stories continually circulated in the German wireless messages about our hospital ships. We have 42 such vessels working to and from the Mediterranean—not 70, as stated in the German press, which pretends that all are heavily laden but not with hospital supplies, and goes on to assert that they are undoubtedly carrying troops and munitions protected by this ruse. The admiralty reply that no hospital ship has carried other than sick and wounded, nurses and medical staff, and stores. Though these vessels are sufficiently ballasted to secure safety and comfort, they are none of them deeply laden—in fact, they are generally some feet higher than deep draught; they are prominently painted in accordance with the Geneva Convention and duly notified to the belligerents. No temporary arrangements, such as have been suggested exist as to any of them. This country strictly abides by the Geneva and Hague conventions, and the report here repudiated is absolutely false and the insinuations are unjust.

The war naturally intrudes into all discussions, practically into all conversations. The Harveian Society has just held a discussion on the organization of the profession for war service when Major Galloway gave some account of the Central Medical War

Committee, which has been formed to deal with matters connected with the present conflict. On it are representatives of the two Royal Colleges of London, the universities of England and Scotland, and the principal medical bodies in Ireland. The director-general of the Army Medical Department has availed himself of the help of this body in recruiting the medical service. Major Galloway urged medical men of military age who were physically fit to join the R. A. M. C. An ex-president of the society, Dr. Charles Buttar, held it to be the duty of every profession to help those of its members who were in any difficulty and that in times of peace, much more during war. He is one of a committee for suggesting methods by which medical practitioners may be set free to serve their country and as far as possible relieved of anxiety as to the effect of doing so on their future. He remarked that generous as the profession is with patients it is very frequently not so with its fellow members. Jealousy and suspicion are by no means uncommon, though the lofty traditions of the calling should render such feelings impossible. Men can be spared from their practice to join for a time the R. A. M. C. with very variable degrees of inconvenience, *e.g.* a single man more easily than a married one, a young rather than old one, one holding an appointment which can be kept open for him on his return, assistants and partners, men in districts crowded with practitioners rather than from rural localities.

To safeguard the interests of those who volunteer for the time of the war the central committee has appointed local committees to which information is being supplied as to various duties devolving upon them and medical men who feel called upon to join the army are urged to put themselves in communication with these local committees. A form of agreement has been circulated as a basis for arranging the conduct of the practice of a volunteer, and it has been suggested by some that partnerships for the term of the war might be formed or a number of men in a locality, perhaps the majority or even the whole, might unite. The president observed that every man in his audience had doubtless asked himself what was his duty in the present emergency and longed for some one to tell him. He submitted that the Central War Committee was the best body to decide the question for any one who felt unable to settle it. His own answer was that every man of military age should send in his name to the committee as willing to take a commission in the R. A. M. C. whenever the committee tells him that it is his duty to do so. This committee is already classifying men in groups according to the ease with which they may be spared from service in the civilian community.

The proposal to include urea in our list of useful remedies may raise a curiosity, not unmixed with scepticism in certain directions, but in these days therapeutists place no limits on suggestions that can easily be subjected to trial. So we have laboratory notes by Professor Symmers and Mr. Kirk on urea as a bactericide and its application in the treatment of wounds. The former shows that it readily kills non-sporing bacteria suspended in water; next that it seems to completely sterilize tuberculous sputum in from half an hour to one hour. Then comes the question, will urea kill bacteria in the presence of blood and such like albuminous material? To decide this, blood was inoculated with *Bacillus pyocyaneus* and urea added, solution being assisted by immersion in hot water for

a few minutes and the mixture left at room temperature for 20 minutes, after which tested on agar and broth tubes. No growth took place, although control experiments furnished confluent growths. But to obtain the bactericidal effect the urea has to be employed in a concentrated solution (25 per cent.). Lower dilutions, however, have an inhibitory effect. W. J. Wilson, in 1907 (*Jour. Path. and Bact.*), found there was no growth of *B. coli* when 8 per cent. was present and with lower percentages remarkable changes of form resulted in different organisms. Urea is stable in the dry state, is practically non-poisonous, highly diffusible, is inhibitive in low concentration (3 per cent.) in higher percentages (8 to 10), is bactericidal, this effect being active in the presence of blood and such organic fluids. Moreover, it does not irritate the tissues and may be sprinkled quite freely and dry over wounds.

To the foregoing Mr. Kirk adds the clinical notes of the use which he and Professor Symmers made during the last four years. In fresh 100 per cent. solution in water they only found it unquestionably beneficial in diphtheria carriers in which its value is recognized. In surgery they met no good results until applied in solid form and freely, too—so that the solution formed in the blood or serum could be kept closely in contact by closing with continuous sutures or covering with a protective to prevent its draining away. Dry dressing arrested the action by absorbing it. Urea is entirely innocuous to the tissues in the strongest concentration or in the dry state. All the wounded soldiers in the Ulster Volunteer Force Hospital were treated with it. Messrs. Symmers and Kirk report that sloughing, infected wounds gave better results under it than otherwise, the circulation around remains normal, no venous congestion, no irritation of skin. Repair, rapid. Sometimes it produces pain, severe enough to demand morphine—the urea seeming to become caked by absorbing moisture from the air. Since using it as a routine dressing in the Ulster Volunteer Hospital the wounds require dressing only once in forty-eight hours and fewer nurses are consequently required.

To sum up the conclusions from the tests employed by the contributors of the preceding report it appears that urea is an antiseptic and acts efficiently in the presence of blood and albuminous fluids; is innocuous to animal tissues; is not toxic in the quantities that can be applied to wounds; saves half the labor necessitated by other treatment; does not retard during use the processes of repair; prevents suppuration arising in wounds from chronic blood infections. From all this striking results ought to be obtained from employing it as a first-aid dressing.

Progress of Medical Science.

Boston Medical and Surgical Journal.

6. Mental Features of Congenital Syphilis. J. H. Bazeley and H. M. Anderson.
7. Diagnostic Value of Lange's Gold Sol Test. Harry C. Solomon, Hilmer O. Koefod, and Edward S. Welles.

1. Symmetrical Synovitis in Hereditary Syphilis.—

Abner Post states that a careful study of syphilitic children shows this symptom to be comparatively frequent. The fact that the joints are seldom fully distended, that they are painless and interfere but little with locomotion explains their infrequent recognition. These joints have been compared to interstitial keratitis which is usually symmetrical, but may be single, or the two sides affected with so long an interval that the first case is single so far as diagnosis and treatment are concerned. Symmetrical synovitis of the knees has occurred so often in conjunction with interstitial keratitis and Hutchinson's teeth that such a triad may be considered as valuable as Hutchinson's triad of interstitial keratitis, Hutchinson's teeth, and deafness. Local treatment of the knees seems to be unnecessary, but constitutional treatment is important. In general, treatment acts slowly. Some cases, not hitherto recognized as syphilis, respond very quickly.

3. Episiotomy.—John T. Williams calls attention to this little used procedure which he states has a definite value in certain obstetric cases. Properly used it should practically eliminate complete lacerations of the perineum from gynecology. It should not be performed except to prevent a complete tear, because incomplete perineal tears heal as well as the episiotomy wound and are less difficult to suture. Complete lacerations of the perineum are to be feared in contractions of the inferior strait; rigid perineum in late primigravidae; short perineum; unusual size of the fetal head; after-coming head in breech presentations, and in face presentations. The incision should be made at an angle of about 45° with the median line of the perineum and not at right angles to it, in order to avoid wounding the venous plexus of the labium and to give the greatest room for extension. The writer has done episiotomy in a number of cases and cites two as illustrative of the entire group.

5. Notes on a Conference on the Medical and Social Aspects of Syphilis of the Nervous System (Continued).—J. H. Bazeley and H. M. Anderson discuss the mental phenomena in general mental states as related to congenital syphilis, the mental phenomena in sixty congenital syphilitic children compared with sixty non-syphilitic children, and the mental phenomena in families with congenital syphilitic children from which they concluded as follows: 1. There is increasing authority for considering the endogenous psychoses and the psychoneuroses to be the last offshoots of luetic heredity. 2. The laboratory findings afford the best classifications of congenital syphilis, and there are six possible groups on this serological basis. 3. Of children under fifteen years constituting social problems, the congenital syphilitics constitute the more serious problems. Among them there are more cases of backwardness in school, there is more feeble-mindedness and retardation, there are more defects in the mental processes (with the one exception of affectivity), there are more delinquencies, there are more defects in vision, hearing, and speech. And if we consider the single individuals with one or more defects, then in the syphilitics there are more individuals with plural defects in the mental processes, there are more individuals with plural delinquencies, and there are more individuals with plural defects in the two main sense-organs and in speech. 4. In families where the syphilitic infection makes its appearance the before and after picture in the mental development of the children is clearly delineated. The writers cite a number of instances in which the earlier children in a family are normal while those coming after syphilitic infection has made its appearance show mental deterioration with the other stigmata of hereditary syphilis.

7. **Diagnostic Value of Lange's Gold Sol Test.**—Harry C. Solomon, Hilmar O. Koefod, and Edward S. Welles review the diagnostic results that have been claimed for the gold sol test and analyze the results of this test in 500 cases from which they conclude that fluids from cases of general paresis will give a strong and fairly characteristic reaction, especially if more than one sample is tested, in the vast majority of cases. Very rarely general paresis gives a reaction weaker than the characteristic one. Fluids from cases of syphilitic involvement of the central nervous system other than general paresis often give a weaker reaction than the parietic, but in a fairly high percentage of cases give the same reaction as the parietics. Non-syphilitics may give the same reaction as the parietics; these cases are usually chronic inflammatory conditions of the central nervous system. When a syphilitic spinal fluid does not give the strong parietic reaction it is good presumptive evidence that the case is not one of general paresis, and this test offers a valuable differential diagnostic aid between general paresis, tabes, and cerebrospinal syphilis. The term "syphilitic zone" is a misnomer as non-syphilitic as well as syphilitic cases give reactions in this zone, but no fluid of a case with syphilitic central nervous system disease has given a reaction outside of this zone, so that negatively it may be used, and any fluid giving a reaction outside of this zone may be considered non-syphilitic. Light reactions may occur without any evident significance, while a reaction of no greater strength may mean marked inflammatory reaction. Tuberculous meningitis, brain tumor, and purulent meningitis fluids characteristically, though not invariably, give reactions in higher dilutions than syphilitic fluids. The unsupplemented gold sol. test is insufficient evidence on which to make any diagnosis, but used in connection with the Wassermann reaction, chemical and cytological examination, it offers much information aiding in the differential diagnosis of general paresis, cerebrospinal syphilis, tabes dorsalis, brain tumor, tuberculous meningitis, and purulent meningitis. In the opinion of the authors no cerebrospinal fluid examination is complete for clinical purposes without the gold sol test.

1. **The Cottage Hospital in Rural Communities.**—Charles P. Nobel says that naturally the broad principles which apply to all hospitals, as to their necessity, management, advantages to the community, and to the medical profession are equally applicable to rural hospitals, but there are, in addition, certain facts and factors which apply to them chiefly or exclusively. The management, while affording efficient medical and nursing care, should provide an atmosphere in which the spirit of helpfulness, true sympathy, charity, and gladness abounds. There is no question that the "closed" hospital can be more efficiently administered; that its patients will receive better and more systematic treatment; that the superintendent of hospital and training school will be spared many trials, and that the medical staff is afforded a much better opportunity to develop additional technical skill and to acquire greater clinical knowledge in the particular

specialties of medicine in this type of hospital. The "open" system as applied to the private rooms, and even to certain small pay wards, has manifest advantages to rural hospitals. With reference to the question whether the local staff shall do the general and special surgery or whether a skilled specialist from a neighboring city should be called in seems best to be settled by following a mixed plan. The local staff should be prepared to operate in emergency cases and will be able to perform many other operations with skill and success, but if skilled specialists are not called in the staff misses the opportunity for improving their own surgical and medical technique. There are three other important matters in connection with the proper conduct of a rural hospital and these are the wisdom of having a paid anesthetist, a salaried pathologist and bacteriologist, and also a properly remunerated x-ray specialist attached to the staff.

6. **Röntgen's Discovery.**—W. D. Coolidge objects to the statement frequently made that Röntgen's discovery was an accidental one and says that the combination of circumstances which led to the discovery of "invisible light" was of Röntgen's own choosing and the results were exactly what he was looking for. Recent developments have made it possible to measure the wave length of the x-rays, and shows them to be a transverse vibration traveling with the velocity of light and with a wave length about one-tenth thousandth that of ordinary light. Moseley and Darwin have found that each element, when placed in the path of the x-rays of sufficiently high penetration, gives off secondary rays with a wave length characteristic of the particular substance in question. This serves not only as a useful method of analysis, but also as the basis of a logical method for grouping the elements. In discussing the future possibilities of the x-ray the writer suggests that their germicidal and sterilizing action may be commercially useful in connection with food products; that they may be useful as ionizing agents to bring about chemical reactions; that as it has been possible to produce the decomposition products of radioactive substances by means of the x-ray, it therefore seems possible that we may be able some day to produce radioactive substances synthetically; that it is not too much to hope that we shall be able to transmute the elements at will and to store up large quantities of available energy in small masses; that the work now being done on alpha ray scattering and with the x-ray spectrometer will lead to much higher efficiency of x-ray production; that another dream which should come true is the production of a substance capable of making a screen a thousand times more sensitive than anything we now have; that with our rapidly increasing knowledge of characteristic radiations, we shall some day see a photographic plate in which a much larger fraction of the x-ray energy is absorbed with a corresponding increase in speed; that with the ability to get characteristic radiations of definite wave length, the germicidal and physiological actions can be scientifically studied, with the possibility of finding out whether there is, for a definite purpose, any specificity of action so that a certain cell responds more strongly to a certain wave length than to any other.

1. **Sanitation.**—W. C. Gorgas, speaking to health officers at the Fifteenth Annual Conference of Health Officers of New York State at Rochester, September, 1915, reviewed the well known facts regarding yellow fever and the stegomyia mosquito and the sanitary work done in Havana and Panama, laying special emphasis on wages as the important factor in determining sanitary conditions. He says that because of the risk that men ran in going into a country where yellow fever was prevalent they were obliged to raise wages and to offer special inducements to get men to work in these localities. If yellow fever had continued they would still be raising wages on the isthmus. This large increase in wages caused a great general improvement in living conditions, and to this improvement in social conditions caused by high wages we owe principally our extraordinary improvement in general health conditions. His experience has taught that it is the health officer's duty to urge forward those measures in his community which will control individual diseases, but it is still more his duty to take that broader view of life which goes to the root of bad hygiene, and do what he can to elevate the general social conditions of his community. This can best be accomplished by increasing wages. The writer believes that every man should receive a "natural wage," which is just what he produces, not a cent more and not a cent less, and that a step toward this ideal condition might be made by taxing unused lands to such an extent that the owners would be compelled to use them. The coming generation of health officers have on their hands the fight for the greatest of all sanitary measures, natural wages.

4. **Diphtheria.**—William H. Park and Abraham Zinger give the late results of active immunization with diphtheria toxin-antitoxin and with toxin-antitoxin combined with diphtheria bacilli. Their recent investigations show that individuals who, before treatment, give a negative Schick reaction are immune probably for life and, therefore, it is not necessary to inject them, when exposed either with antitoxin or toxin-antitoxin. Those who give a positive reaction and are exposed to diphtheria and in immediate danger should receive either antitoxin alone or, if a longer protection is desired, both antitoxin and toxin-antitoxin. For the general prophylaxis against diphtheria in schools and communities, excluding immediate contacts, a mixture of toxin-antitoxin alone (from 85 to 90 per cent of the L+ dose of toxin to each unit of antitoxin) or toxin-antitoxin plus vaccine of killed diphtheria bacilli is recommended. The dose is 1 c.c. of toxin-antitoxin and 1,000,000,000 bacteria injected subcutaneously and repeated six times at intervals of six or seven days. Sufficient time has not yet elapsed to judge the value of adding the injections of the bacilli to the toxin-antitoxin. The early and the late results of active immunization should be determined with the Schick test. Early results are those obtained by the application of the test within four weeks, and late results from four months to two years after the immunizing injections.

5. **Opium Derivatives.**—Henry K. Pancoast and Arthur H. Hopkins have found that Röntgen examina-

tion is a valuable method of studying certain phases of drug effects on the gastrointestinal tract, especially motility, and the knowledge it furnishes can be gained better by this method than by any other. Their observations were made in a series of 11 cases given morphine and one heroin habitué. While they have been able to duplicate the phenomena observed by others, with one exception, there was a decided lack of uniformity in connection in the effects produced in different individuals, in connection with both stomach and bowel. There is no distinct uniformity in connection with dosage. Small doses in some may produce more marked effects than much larger doses in others. Females appear to be more susceptible than males. In the stomach a rather high spasmodic hour-glass contraction is observed rarely, but the writers have not seen this near the pylorus as described by others. In some instances the stomach may show no appreciable change from normal. In most cases there is more or less pyloric spasm, increased peristalsis and a decided prolongation of the emptying time. In the small intestine, morphine causes decreased motility almost uniformly, apparently as a result of a lack of propulsion and not of spasm. When marked it is most noticeable in the upper small bowel. The effect on the large bowel is very variable and probably of little consequence. Oral administration produces practically the same effect as subcutaneous injections.

6. **Endowment of Childhood.**—John F. Moran points out that among the results of advances in obstetrics are the awakening interest in prenatal care and the prevention of infant mortality, the practical abandonment of craniotomy on the living child, and the broadening indications for cesarean section. He finds that practically 38 per cent of the deaths under one year of age are due to causes mainly dependent upon the health and condition of the mother during pregnancy and confinement. Much good is being accomplished by organizations engaged in seeking the welfare of motherhood and childhood, by stimulating general interest in the cause and securing lay and professional co-operation; but if this much-to-be-desired beneficence is to become nation-wide, the checking and follow-up system can be satisfactorily done only under state subsidy and control. The keynote to decreasing the appalling infant mortality is good obstetrics and the watchword is efficiency—efficiency in prenatal care—so that at the time of birth both mother and child shall be in the best possible condition, and efficiency in the conduct of labor whether it be in the rôle of "watchful waiting" or masterly activity in order that the child shall be assured the inalienable right to be born alive and healthy and that the mother may be properly safeguarded.

8. **Rectal Examinations in Labor.**—Rudolph Wieser Holmes expresses the opinion that there must be a complete revision of the chapter on pelvic examinations in obstetric textbooks which shall give adequate presentation of the value of rectal examination. Vaginal examination should be made subordinate to rectal touch. While, at the present time, rectal examination does not give us the means of measuring pelvic size, it is of great value in estimating the factors situated in the posterior half of the bony pelvis. In almost every direction, under appropriate conditions, rectal examination is as definite as vaginal, if combined with abdominal palpation. The ease or difficulty of rectal examinations are commensurate to the ease or difficulty which encompass the vaginal ones, and are dependent on the same factors. Rectal examination is an utterly innocuous procedure in labor, whereas, vaginal examinations are always potential sources of infection to the woman. Rectal examinations are peculiarly appro-

priate to those women who are to receive the test of labor in relatively contracted pelvis when cesarean section may possibly be needed. Vaginal examinations should be made in labor only when the rectal examination, for some special reason, is indefinite and inconclusive. The rectal examination is a decided technical advance in the conduct of labor.

9. Dysenteric Amebas in Rats.—Kenneth M. Lynch records observations which he has made incriminating the rat as a factor in the dissemination of amebic dysentery. The details of his study warrant the conclusions that: 1. The rat (*Mus norvegicus*) suffers from spontaneous amebic dysentery similar to that occurring in man. 2. This apparently occurs in endemic foci in Charleston, S. C. 3. The ameba found in the cases of rat infection here reported are indistinguishable from *Endamoeba histolytica*. 4. This rat may be infected with *Endamoeba histolytica* by allowing it to eat human feces containing this parasite. 5. The disease thus produced is practically the same as that occurring in man and from spontaneous infection in rats. 6. This infection, spontaneous and experimental, may be transmitted from the infected to the healthy rat by close association, that is, living, eating and drinking together. 7. The rat is a possible and probable disseminator of dysenteric amebas pathogenic for man.

7. The Development of the Oocyst of the Human Coccidium. C. M. Wenyon.

1. Modern Gynecological Practice.—Victor Bonney epitomizes the principal advances that have been made in gynecology during recent years, and presents a bird's-eye view of modern gynecological practice. He especially emphasizes the metamorphosis that has occurred within the memory of all. Gynecology was formerly a branch of medicine. It has become the most surgical of all branches of surgery. Specialists are a necessity for the advancement of any science or art, but in gynecology, at all events, pure specialism is a danger. The abdominal cavity is full of surprises, and except of necessity no one should open it who is not competent to deal with whatever he finds there. Hence the necessary enlargement of scope of the modern gynecologist. He is to-day an expert abdominal surgeon, especially expert in the pelvis.

2. Arteriovenous Injury.—G. A. Wright reports these cases because arteriovenous injury leading to communication between two vessels are not now of rare occurrence and records are needed to enable them to formulate rules for their management. Experience in the South African War brings out certain points. 1. It is not always possible to make out the aneurysm even though such may exist. 2. In aneurysmal varix the venous dilatation may not appear for a considerable time, several months or more after the injury, and in such cases, usually no operation is called for unless permanent disturbance of the circulation, quick pulse, etc., are present. 3. In late cases, those in which the injury has been inflicted perhaps some weeks before, at least in those in which the external wound has healed, when an operation is called for, several courses are open to the surgeon. Of these the most successful seem

to be: (a) Ligature of the artery above and below the communication, leaving the vein alone. This was the course adopted in the first case cited. (b) Ligature of both vessels above and below. (c) Incision of the sac and ligature in the sac of both vessels above and below. Proximal ligature of the artery alone seems, in cases of arteriovenous communication, to give the worst results. The more recent conclusion of Inspector General Delorme is in favor of incision of the sac, and ligature in the sac of both vessels above and below.

3. Diagnosis and Treatment of Mediastinal Pleurisy.—Louis Renon reports a case in which the diagnosis of mediastinal pleurisy was easy simply because the possibility of its being such a case was present in his mind, skiagraphy having merely confirmed and rendered certain the diagnosis. In arriving at a diagnosis of this condition the first thing is that the possibility of its existence should cross the mind. The diagnosis of mediastinal pleurisy can be arrived at on a reasoned practical basis if one carries out seriatim the following examination. In the course of an acute febrile affection any sign of compression within the mediastinum should lead one to entertain the idea of a solid or liquid tumor in this region. This will occur to one even more markedly when the mediastinal syndrome is complete, that is, compression of the trachea, the esophagus, the nerve trunks, the vessels, etc., and is manifested by attacks of suffocation, retraction, amphoric breathing, paroxysmal cough, disturbance of voice and of the complementary thoracic circulation. The finding of this syndrome should be followed by x-ray examination. Bronchoscopic examination is indicated in the presence of amphoric breathing. The writer dwells somewhat at length on the difficulties of differentiating between dermoid cyst and mediastinal pleurisy and states that when one feels certain that he is in the presence of an encysted purulent effusion in the mediastinum, that in spite of the difficulty and risk of operation, there is no alternative when the temperature remains high, pressure effects produce an intense mediastinal syndrome, and, especially when by the twentieth day nothing has been coughed up.

4. Clinical Results of 1,000 Intravenous Injections of Galyl.—Harold Spence states that galyl, or tetraoxydiphosphaminodiarsenobenzene is one of the several synthetic substitutes for salvarsan. Its arsenic content is 35.2 per cent, and it possesses some claim to originality in that it contains in its formula phosphorus (7.2 per cent) while the atoms of arsenic are graphically represented as differently grouped. The assertion is made that it has the advantage over other arsenic derivatives of being non-toxic to nerve tissue. Several cases are cited as typical of the series and from them it appears that galyl is at least as efficacious as its predecessors and that syphilitic lesions disappear rapidly under its use. It is also claimed that it is less toxic than salvarsan. Thus far no fatality has been reported from its use, neither has there been reported any undoubted case of arsenical intoxication, but the remedy is new and the literature very meager. An interesting complication encountered twice in the series was a reaction resembling serum sickness.

5. An Epidemic of Jaundice Occurring at Alexandria.—E. B. Gunson and J. W. C. Gunn relate that during the months of June, July and August, 1915, they observed and treated a large number of cases of jaundice admitted to the general hospital at Alexandria. These cases were of great interest in that they arose almost without exception from a single camp. The clinical picture was so constant and differed in so many respects from that of ordinary catarrhal jaundice that the authors regard the disease as a definite clinical

entity. The most striking feature in the clinical picture was the marked enlargement of the heart in practically all the cases. This enlargement was so definite and so persistent, associated as it was with giddiness and dyspnea on exertion, as to make it almost the leading feature in the clinical picture.

6. Pneumosan in the Treatment of Pulmonary Tuberculosis.—A. E. A. Carver makes a supplemental report on a series of cases of pulmonary tuberculosis treated with pneumosan upon which he promised to report after an interval to what extent the initial favorable effects in these patients should be maintained. He now announces that the results of this treatment have surpassed his expectations. After the lapse of 16 months, all but 16 of the 103 showed a continued improvement. He states that one great point in favor of pneumosan is that he has never known it to be followed by untoward effects. The results appear to warrant its more extended use in pulmonary tuberculosis, though, like every other remedy, it should be used in conjunction with careful supervision of the patient's home condition and not as though it were sufficient in itself to restore the patient to his normal state.

2. Organic Lesions from Shell Concussion.—J. Jameson Evans states that as far as cases of shell concussion concern the eyes, the main symptoms are impairment of sight, contraction of the visual field, photophobia, and blepharospasm. When these symptoms are noted with little or no evidence of injury to the eyes or neighboring cavities, it is usual to regard them as functional, and in the majority of cases this view is correct. It must not be assumed that they are all of this nature. Cases are met in which there is little or no evidence of injury but which show gross changes such as dislocated lens and detached retina in the eye, but the histories of these cases have not been sufficiently definite to ascribe these changes to concussion. Shell shock also seems capable of bringing out latent ocular defects; squint and nystagmus have become manifest after shell fire, although the patients deny their previous existence. A number of cases are reviewed which the writer believes indicate the necessity of investigating cases of shell shock very carefully in order to differentiate those that are functional from those that are due to organic lesion.

4. The Prophylaxis of Tetanus.—A. T. MacConkey summarizes the literature on the prophylaxis of tetanus to date. He says that allowance must be made in the reports that have come in for the incomplete details of results due to the exigencies of the times. Taking this into consideration and putting the figures together he finds that among 83,593 wounded there were 539 cases of tetanus, or a percentage of 0.65. In the Crimean War, tetanus occurred in 0.15 per cent of the wounded; in the American Civil War, in 0.2 per cent, and in the Russo-Turkish War, in 0.12 per cent. Thus the incidence of tetanus in the present war is greater than would have been expected. The experience gained during the first year of the war confirms the opinion

that from 500 to 1000 U. S. A. units of tetanus antitoxin is a sufficiently large prophylactic dose for the majority of cases, and that it is advisable in severe wounds to repeat this dose once or twice at intervals of a week. Occasionally cases occur in which antitoxin appears to have very little preventive effect. These cases should be recorded with minute details, so that our knowledge of them may be increased and an explanation of their occurrence obtained. Those cases of tetanus which develop some weeks after the receipt of an injury may be due to the reactivation of a quiescent focus or to too early or too energetic active or passive motion. The question of the duration of passive immunity is still unsettled. In one case the evidence shows that 12,000 U. S. A. units protected for only thirteen days and in another that 1,500 U. S. A. units conferred immunity for three weeks. As regards operating in cases of tetanus, the opinion before the war was against doing so, and nothing has occurred since to change that opinion.

6. Spinal Injuries of Warfare.—Gordon Holmes, in this, the third Goulstonian Lecture, discusses the sensory disturbance of spinal injuries, under the headings of "remote" and "local" sensory disturbances. He states that there is no one sign or symptom from which one can draw reliable conclusions on the severity of the lesion, or from which one can say, when there is complete motor and sensory paralysis, as there nearly always is in the earliest stages, whether the cord is completely divided or not. The structural damage is not always parallel to the functional loss. The most reliable information is perhaps given by the state of the muscles of the lower limbs; after three or four days the legs are usually very flaccid and their muscles toneless when the lesion is severe and irrecoverable, and they gradually become more so and waste. The preservation of tone in the muscles, is an indication that improvement may be expected. Valuable information can also be obtained by stimulation of the soles, as the amount of reflex movement that results varies more or less inversely with the severity of the injury. When tactile stimuli can be felt in the lower limbs within the first two or three days there is promise of useful recovery. A large proportion of the cases of spinal injury die soon after the infliction of the wound from the shock or associated wounds of the abdomen or chest. Among those that survive the greatest danger is from cystitis and pyelonephritis and the development of extensive bedsores. A large part of the responsibility therefore falls on the nursing. When cystitis is threatened or has developed, the writer has seen excellent results from suprapubic drainage. Finally, the danger of moving the patient must be borne in mind; the risk is obvious if the vertebral column is fractured. There is evidence that secondary changes are more liable to develop after movement; absolute rest is consequently advisable during the first few weeks if the symptoms hold out any prospect of useful recovery.

7. A New Cataract Operation.—M. Corry writes a preliminary note on a new operation which is now being performed in Delhi. The essential feature of this operation is a preliminary conjunctival flap cut so as not to hamper the movements of the knife in making the incision in the eye-ball. The lens is removed entire in its capsule either with or without a preliminary iridectomy. The advantages of the operation as shown by the results obtained in 1500 operated upon this year are: 1. The wound in the eye-ball is closed at once by the flap so that the risk of subsequent infection is *nil*. 2. Prolapse of the iris and vitreous are prevented from occurring. 3. The flap is firmly adherent to the globe

within a few hours, and in a large majority of cases the dressing can safely be then removed. 4. Cataract cases are now treated in this hospital as out patients, and they can go home immediately after operation, returning next day to have the dressing removed permanently. 5. No photophobia is present subsequent to the operation, even on the second day, when the patients are provided with glasses, and can see well. 6. The usual corneal astigmatism is very much less than is generally found after other operations.

Münchener medizinische Wochenschrift.

November 9, 1915.

On the Treatment of Deficiency Phenomena.—Engelhorn refers chiefly to the menopause which has been studied as exhaustively by Jaschke among the moderns. The simplest explanation of some disagreeable phenomena of the menopause is that there is an overaction of the antagonists of ovarian internal secretions. The critical question is as follows: to what extent are the phenomena of the menopause due to ovarian insufficiency and to what extent to "overcorrection" by the antagonists. But certain endocrin glands are believed to act as understudies of the ovaries, so that defect symptoms are automatically cut down. Other views are in evidence—thus if ovarian inner secretion has held in check some psychoneurosis, then removal of the ovaries sets it free. More strictly speaking, the psychoneurosis may develop in the latter end of the fourth decade simply as a coincidence. Why must it be imputed to the cessation of the menses? An intensive study of the results of castration of women has failed to show any sequential changes in the activity of other endocrine glands. The remedies useful in the menopause comprise hygiene, nerve sedatives and organotherapy. The former may include a vegetarian diet and systematic hydrotherapy. Nervines include bromides and phenacetin and valerian derivatives. Ovarin and lutein are given as organotherapeutic resources. An old resource is venesection at stated intervals (6 weeks to 3 months). The author after taking the blood pressure may, if it be indicated, withdraw 100 c.c. of blood from the cubital vein as a valuable palliative for the nervous phenomena of the menopause. Finally regarding the amenorrhea and ovarian dysfunction of young women as in part due to deficiency, the author even justifies venesection in some of these cases. The association of neurotic manifestations and venesection obtains throughout.

Treatment of Sepsis.—Jessen has already advocated 1 per cent intravenous injections of lactic acid in tuberculosis and has recently extended this treatment to streptococcus and staphylococcus sepsis—non-fulminating cases. The examples cited by him would ordinarily be classed as rheumatoids, such as are naturally refractory to salicylic acid; together with tuberculous subjects in the hectic fever stage. In such cases the acid exerts a bacteriolytic power. As a preliminary to such treatment any pus focus should be disposed of. Further in regard to salicylic therapy the author holds that the salts are of little value and that the salicylic acid should be given pure and in high doses. Thus given, however, it produces burdensome by- and after effects, more so than does lactic acid when given intravenously. The conditions controlled by lactic acid seem to be "septoid" rather than septic. The diagnosis of sepsis is based largely upon the septic facies (greenish tint with blue lips together with embolic processes in the skin and about the joints). Bacteria in the blood are not mentioned, but a bacteriolytic effect is assumed when the temperature suddenly falls.

Night Blindness in the Battlefield.—Paul mentions the fact that nyctalopia has often been seen to attack perfectly intact soldiers. In peace times on the contrary it is very rare and tends to appear only in the broken down. Neurasthenic soldiers make up many of the army cases. The prognosis is extremely uncertain and it is a problem to know what to do with the victims. "War nyctalopia" is first of all not a disease of the eye but is the result of nervous relaxation and psychic depression. Prognosis must to some extent depend on protection from nervous and psychic insults.

Deutsche medizinische Wochenschrift.

November 4, 1915.

Typhus, Typhoid, Malaria, etc.—The leading articles in the present number deals with these subjects. Otto gives an account of a typhus epidemic in a prison camp. On March 2 last six cases were recognized, after some suspects had been received. The six were found to have come from the same locality, which suggested louse propagation. All who had come in contact with the strangers were at once isolated, and their barracks closed. An anti-louse campaign was now instituted. A barbed wire fence quarantine was also established. The anti-louse campaign was extended to the unexposed troops. The barracks of the exposed men were washed and treated with naphthalin. It was apparently impossible to rid the barracks of lice while the men were in them. New ones were therefore gotten up as a sort of detention hospital. These were provided with steam disinfection as well as baths. The occupants of the various barracks could be cleaned up here, while their domiciles were subjected to a rigorous disinfection, along with clothing, linen and bedding. Suspects were at once moved into a special barracks and if typhus developed were at once transferred to the pest house proper. No one entered the latter unless he was louse free—hence physicians and attendants were protected, and as a matter of fact not a case developed among them. In addition to the 6 patients who entered the camp with typhus 56 others developed the full picture of the disease while 9 others without examination were pronounced infected, a total of 71 cases. The wisdom of segregation of suspects and exposed was apparent, because men developed the disease in all quarantined places and could readily have carried the disease to the unexposed. The article will be continued. Drs. Hage and Korff-Petersen consider the subject of typhoid immunization and diagnosis. The immunized were tested for agglutination and complement deviation as well as the blood picture, diazo and attempts to cultivate bacilli from the blood. Those who escaped typhoid after vaccination are contrasted with those who developed the disease. Of the five tests used but one, the diazo, seems to have an absolute value as it is as good as absent in all subjects who have been immunized.

Chronic Pancreatitis.—Einhorn of New York finishes his article on this subject. Prognosis depends practically upon whether nutrition can be maintained. In certain cases secondary to diseases of the biliary passages, surgical relief of the latter may arrest the disease. The patient's nutrition can be improved if a certain amount of pancreatic gland tissue remains. The state of the stomach is also of great significance in these cases. There may be hypo- or hyperacidity or hypochylia, and indications are thus furnished for special diet and medication. Preparations of pancreas often have a very salutary action. In lientery, suggesting as it does very weak digestive powers, the nourishment should at first be liquid.

Book Reviews.

TWELVE LECTURES ON THE MODERN TREATMENT OF GONORRHEA IN THE MALE. By DR. P. ASCH (Strassburg). Translated and annotated by FAXTON E. GARDNER, M.D., Lecturer and Assistant Visiting Genito-Urinary Surgeon, New York Polyclinic; Assistant Genito-Urinary Surgeon, Bellevue Hospital, Outpatient Department, New York City. Price, \$1. New York: Rebman Company, 1915.

THE title of this book conveys a fairly accurate idea of its contents. The author modestly claims in these unpretentious lectures to draw attention to those methods of treatment of gonorrhea which have proven most reliable in his practice. Much of value is contained in the chapters on acute prostatitis and epididymitis. The translator's notes temper the author's radical statements concerning serum and vaccine therapy and frequently suggest modern instead of obsolete surgical procedures.

HEREDITY AND ENVIRONMENT IN THE DEVELOPMENT OF MEN. By EDWIN GRANT CONKLIN, Professor of Biology in Princeton University. Price, \$2, net. Princeton: Princeton University Press, 1915.

THE best presentation of a scientific subject in a non-technical way will be given by one who is most deeply versed in that subject. The country is flooded with "popular science" *ad nauseam*, but there are few books to which the thoughtful, educated reader may turn for an adequate, clear, and simple statement of the results obtained by the intense activity of scientific specialists, which is the characteristic feature of present-day culture. Fortunately this need has been recognized by several persons with large means and generous dispositions, and the result has been the endowment of lectureships of sufficient importance to secure the services of men of the first rank. One of the most fruitful of these endowments is "the Norman W. Harris Lectures at Northwestern University," and the book under review is the latest published result of that endowment. It is a worthy companion to the notable volumes previously contributed to the series.

Of all the sciences, Biology is the one that most directly concerns mankind. In its applications it affects every individual. Yet to many educated persons "biology" is a strange word, and the language of the science is an unknown tongue. This book should do much to dispel this ignorance. In a small volume that can easily be held in the hand, we have here the fundamental facts and theories that are of interest to everyone. The first chapter deals with the process by which the individual arises from the germ, the general principles of development. The second chapter is of especial importance for it deals with a subject that is but little understood outside of biological circles. This is the physical basis of heredity and development, including the nature of sex, the origin and behavior of the sex-cells. The two chapters following contain a description of the phenomena of heredity, and a discussion of the relative importance of heredity and environment in the development of men.

Having mastered so much, the reader will be prepared for the discussion in the remaining chapters. These are the ones that probably will be read with the greatest interest. First comes Eugenics, the preservation and improvement of the race by the control of heredity. Here is a sane, leved-headed view of the subject, a relief from the clamor that this subject has called forth in the popular press. Finally we have a discussion of the bearing of these biological principles upon the ethical view of life, upon the questions of personal responsibility, freedom of the will, and determinism.

It is impossible to state scientific facts clearly without using some words that are unfamiliar to the untrained reader. But the book is made complete in itself by the addition of a glossary, as well as a bibliography and an index.

As a whole the book gives in a small space a remarkably clear and adequate statement of the general belief of biologists concerning the fundamental principles of their science. The only exception is in regard to the effect of selection. A modification of the statement made on page 379 becomes necessary in view of a more recent article by Castle (*American Naturalist*, December, 1915). The style of the book is interesting and attractive and the subject matter of the greatest im-

portance. It is a work that should be read by every physician, and it is one that can be recommended to many patients to their pleasure and profit.

PHYSIOLOGICAL CHEMISTRY. A Text Book and Manual for Students. By ALBERT P. MATHEWS, Ph.D. Professor of Physiological Chemistry, The University of Chicago. Illustrated. Price, \$4.25. New York: William Wood & Company, 1915.

UNLIKE most of the books that have been published under the above or similar titles, this volume is truly what it is supposed to be—a treatise on the chemistry of physiology in all its aspects. Frequently the authors of such works are primarily chemists, less often primarily physiologists, and in either case the result, excellent as it may be from the standpoint of either specialty, does not present the fusion of the two sciences that is intended. Professor Mathews, however, is evidently entirely competent to compose either a text book of physiology, or one embodying the most advanced teachings in organic chemistry and physical chemistry, and having written the two simultaneously, presents them skillfully interwoven between the covers of the present volume. Consequently the mass of chemical lore that requires discussion is invested with a vital interest that it all too often lacks in other books, while at the same time the physiological observations receive their adequate explanation in the underlying principles of pure science. The book is divided into three sections. Of these, the first is devoted to the physics and chemistry of living matter in general, as exemplified in protoplasm and the cells. In the second and largest portion of the book, the functions and activities of the mammalian body are discussed in full detail, and the third section contains a complete and very useful epitome of the almost endless technical procedures that are now necessary in making tests of metabolism and organic function. Where everything is excellent it is difficult to select portions for special praise, but no doubt most readers will find the sections on calorimetry, on the blood, and on general metabolism particularly instructive. The list of references appended to each chapter is of great value, to both students and research workers, as they comprise books suitable for collateral reading, as well as a satisfactory bibliography of each topic. Some mention should also be made of the admirable mechanical execution of the book. Although it contains over one thousand pages, the size and weight have been kept within astonishingly low limits by the use of a very thin but perfectly opaque paper, and the many illustrations are admirably reproduced. The text throughout embodies the most recent views and theories, and is without a doubt the most satisfactory exposition of the subject extant, while the author's most agreeable narrative style makes the book a delightfully easy one to read.

WHAT TO EAT AND WHY. By G. CARROLL SMITH, Boston, Mass. Second Edition. Thoroughly Revised. Price, \$2.50, net. Philadelphia and London: W. B. Saunders Company, 1915.

THE importance of diet in the prevention or treatment of disease is now so thoroughly recognized that books on diet have multiplied rapidly within recent years. However, there is always room for a good article of any kind and this statement applies to Mr. Carroll Smith's book. It is an excellent common sense dissertation on diet, avoiding technicalities and the chemistry of foods but discussing exhaustively the value of diet in certain diseases and affections and pointing out the kind of food most suitable in their prevention and treatment. The book will well repay a careful reading.

THE ETIOLOGY OF TYPHUS EXANTHEMATICUS. By HARRY PLOTZ, PETER K. OLITSKY and GEORGE BAEHR. Reprinted from the *Journal of Infectious Diseases*, July, 1915. pp. 1-68, with one plate.

IN the small book under review are described at length the investigations pursued by Dr. Plotz and his coadjutors Drs. Peter K. Olitsky and George Baehr which terminated in the discovery of the typhus bacillus. The conclusions reached as the result of these investigations would seem to justify the claim that the bacterium isolated by Plotz is the causative agent in typhus exanthematicus. For those who desire to judge for themselves as to the validity of the claim, a perusal of the book will demonstrate that Plotz and his co-workers have fulfilled all the scientific predicates calculated to place their conclusions on a sound basis.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Ninth Annual Meeting, Held at Dallas, Tex., November 8, 9, 10, and 11, 1915.

THE PRESIDENT, DR. OSCAR DOWLING OF SHREVEPORT, LA., IN THE CHAIR.

Report of Committee on Prevention and Treatment of Pellagra.—DR. H. LESLIE MOORE, chairman, of Dallas, Tex., stated that taking everything into consideration they had come to the conclusion that the ideas advanced in the experiments made by Dr. Joseph Goldberger of the Public Health Service, were the most plausible, and probably the only theory that had come anywhere near being proof. When he spoke of proof, the members doubtless noticed a few days ago a report came out in the Mississippi Board of Health in which a number of convicts had had the disease produced in them by Dr. Goldberger according to his theory. They had all noticed that nearly every case of pellagra occurred in people who were poor and who were not able to get the best nourishing food. Very few cases occurred in the well to do. This fact Dr. Goldberger had observed. He observed in certain orphanages that this took place in Mississippi where there were a large number of children who had pellagra, and that nearly every case, all of the cases practically, were confined to those between the ages of six and twelve years of age. He set to work with a view of determining if these children were fed differently from the older children and he found that the children of this group were fed very little lean meat or other animal protein foods, and were given mostly biscuits, light meal, syrup, and very little of the legumes, such as beans and peas. In one of the largest orphanages he found there was the highest percentage of pellagra. Following this the Public Health Service took charge and prescribed a diet for those children between the ages of six and twelve, and they were given a greater proportion of fresh animal food and all the leguminous protein foods, beans and peas, etc., in addition to what they were already getting. In those children who survived through the spring and summer the trouble would apparently clear up to reappear the following spring. In the two institutions there were probably 200 cases of pellagra which were fed as prescribed by the Public Health Service. After this additional diet was prescribed, only one out of these 200 cases recurred the following spring, that is, they went one entire year without recurrence with only one exception. Dr. Goldberger, concluded that pellagra could be prevented by appropriate diet without any change in environment, whether it be hygienic or sanitary. In other words, there was no change in the environment in any of these cases except the addition of the diet. No attention was paid to the sanitary condition.

Report of the Committee from the State at Large.—DR. W. L. ALLISON, chairman, of Fort Worth, Tex., stated pellagra had spread rapidly through the entire South since 1907, until now each of the Southern States could number its cases by the tens of thousands. The medical profession was better acquainted with the disease now, and therefore its presence was suspected and diagnosed earlier than formerly. While it was true that in Europe the disease was largely among the poorer classes, this did not hold true in this country, and especially was it not true in Texas. They had no such poor in Texas as were found in Italy, and the disease was frequently found among the well-to-do classes of people there. They had every reason to believe the disease was not directly contagious. It was a significant fact that with few exceptions, nurses and doctors handling these cases in the various institutions where pellagra was treated, had not contracted the disease. Notwithstanding the many theories as to the cause of the disease, none had as yet been proven. Like many other diseases, a low diet and a run-down constitution seemed to be predisposing factors. That the disease was purely a dietary one was advocated by many, but this theory would not account for all the cases, nor would it explain its sudden incidence and rapid increase in this country. Many had developed the disease with whose diet no fault could be found. Corn as a dietary factor seemed to be losing favor. The occasional failure of mild cases to respond promptly to a well-balanced diet, would seem to discredit any dietary

theory. The theory of Alessandrini and Scala that "pellagra is nothing more than a mineral acidosis," due to an excess of silica or alumina in the water, had met with little favor and did not seem to be supported by facts. That the disease might be an infection seemed to be gaining favor and had much to support it. The Thompson-McFadden Pellagra Commission pointed to the significant fact that no new cases developed in those mill villages having a water carriage sewerage system. This commission also reported that close connection with a previous case existed in 80 per cent. of their cases. There was nothing to show that the disease was hereditary. Morphine habits seemed fairly susceptible. The incubation period of the disease seemed to be from two to six weeks. All animal inoculation experiments had been negative with possibly one or two exceptions. The greater prevalence of the disease among women between the ages of 20 and 45 made it appear that the causative agent was to be found about the home in the day time. The symptoms of the disease were all in the nature of an intoxication more or less chronic in its course. In the majority of cases the diagnosis should be made before the skin lesions developed. When the disease first appeared in this country, 60 per cent. of the cases died, while to-day probably of these 80 per cent. get permanently well. The prognosis for complete recovery was more favorable in children and it diminished with age, being very unfavorable in old age, although even the old got well. In view of the rapid increase of pellagra, more attention should be paid to the prophylactic treatment. Everything should be done to improve the sanitary and hygienic conditions about the home. A well balanced and nourishing diet would do much to increase the individual resistance and prevent the disease even if it were of infectious origin. A sanitary water carriage sewerage system was certainly a step in the right direction. Active treatment of a case of pellagra should be begun by placing the patient in bed for at least a few weeks, depending on the severity and progress of the case. This of itself lessened the force of most diseases and conserved body energy. Hydrochloric acid should always be supplied where it was diminished or absent. Of the many remedies, thymol, quinine hydrobromide, picric acid, and the arsenical preparations, especially sodium cacodylate, were apparently the most popular.

Pellagra in Texas.—DR. K. H. BEALL of Fort Worth, Tex., stated that while a conservative alarm had been sounded throughout the State by a few, the State Government had done very little to check the ravages of this new enemy. Eight years ago this disease was purely of academic interest to them, although last year it killed 500 of their citizens and made invalids of many thousands more. Texas had within her confines a great many varieties of soil, climate, and altitude. Navarro County had a great many more deaths from pellagra than had El Paso County, although Navarro County had six or seven times as many cases of the disease. There were several factors which might be considered why this occurred. One was altitude, another the climate, but certainly it was not the water because El Paso had a large river and many irrigation ditches. The whole Pan Handle of Texas was free from pellagra because perhaps the altitude was greater than in this part of the country, and therefore along with the high altitude there was a cooler climate. In a chart which he had to show the members there were 1769 deaths, with exactly the same number of females as males between 60 and 70 years of age. Statistics would seem to show that women were much more frequently attacked with the disease when of certain age than men of certain age, or when they became much less resistant to its ravages. An intensive study of pellagra would be extremely fruitful at this time and would lead to much greater results than it would ten years from now, with a study of its epidemiological features, such as heredity, poverty, alcoholism, and syphilis, and the State of Texas had no right complacently to watch this enemy slay the people. No one knew but that in Texas and in this southland pellagra might find a ripe field than in Italy.

Drugs in Pellagra.—DR. W. T. WILSON of Navasota, Tex., reported 500 cases of pellagra treated up to November 1, 1915, ranging from the mild to the severest type. One hundred and ninety cases were treated by himself and 310 treated by other physicians. Of this number 35 had died. Of the 35 deaths, 14 reported death due to pellagra that were treated with picric

acid; ten were terminal cases and of the typhoid type, and died within 14 days after treatment was begun; 4 had tuberculosis associated with pellagra. Two had nephritis complicating. The others, probably cancer, were very young children. In several of them symptoms of pellagra were relieved. Thirty-seven were reported with severe mental symptoms that recovered. His report was not complete on the number of cases improved or not improved. He failed to ask for this data, but from conversation with many physicians he did not think the percentage in either case would exceed 7 per cent. if it even ran that high. From May 4, 1914, the total number of cases discharged to June 9, 1915, were 200 with 3 deaths. He was unable to account for this low death rate except that he had asked for a report on completed cases to June 9, and the seriously sick were probably under treatment at this time. The disease did not become very serious before the middle of May. The total number of cases from June 9 to November 1 were 300. Out of these 500 cases, there were 35 deaths. Of last year's cases treated by other physicians as well as himself, 22 out of a total of 92 had symptoms of a recurrence. This report was almost complete. In each case they had been treated but a short time, averaging about 21 days, and again on being put on treatment this year they responded immediately. There had been reported a total of 35 deaths this year to November 1, most of these deaths having occurred during the months of July, August and September. In acute pellagra or in pellagra of recent origin picric acid was of no value, that is, when used internally and as a gargle. In severe types or those with malarial symptoms quinine hypodermically should be used first, then the picric acid following. In the chronic forms alternate or give at the same time picric acid as above stated and sodium cacodylate hypodermically, and also give the patient some bicarbonate of soda at intervals. Several physicians reported good results from the use of thymol in the treatment of this disease.

The Blood in Pellagra.—Dr. BEVERLY YOUNG of San Antonio, Tex., said that the red cells, hemoglobin, and hemoglobin index varied greatly, and while the total red count was made in nearly all cases, he considered it of only relative importance as the severity of the diarrhea had such a marked effect on the concentration and possibly on the distribution of the cellular elements of the blood. Taking the peripheral blood, however, as an index, the small mononuclear leucocytes were markedly increased, while the other cells, except the polynuclears, were slightly, if at all, affected. Some cases showed slightly high eosinophilia, but this was very variable, and in every case where the eosinophilia was marked he was able to find the ova of intestinal parasites. His observation was that a high lymphocyte count was usually of good prognostic import. This high count usually persisted not to the same extent, but above normal, for weeks and sometimes months after the acute symptoms subsided and the patient was in excellent physical condition. The cases developing after admission to the hospital with two exceptions were among those who were fairly well nourished and eating a well balanced diet, and several cases observed during the same period of time who persistently refused nourishment of any kind did not develop pellagra, and while the lymphocytes were increased in these cases, they were neither so markedly nor so persistently increased as in the pellagrins. Two of these cases were particularly important for comparison since so persistent were they in their fast, that they died of exhaustion in spite of forced feeding.

Etiology of Pellagra with Reference to Amebic Invasion.—Dr. W. A. DEARMAN of Long Beach, Miss., said that while Dr. Goldberger was of the opinion that pellagra was caused by the lack of a well-balanced ration and that as a prophylactic as well as a curative measure individuals should be encouraged to eat liberally of peas, beans, and other legumes, and that the whole solution of the pellagra problem depended on this vital and important principle, this theory was not supported *in toto* by the end results of the Thompson-McFadden Commission. In six mill villages studied, comprising 861 families, of which 140 contained one or more cases of pellagra, the daily use of fresh meat was rather uncommon in the population, only 13 families falling in this group, almost half of the families (428) used it rarely or never. The families containing cases of pellagra occurred in all the groups and were relatively most numerous in the group using fresh meat daily and less numerous in the summarized group using

the food rarely or never. In those families avoiding fresh meat altogether, only 4 out of a total of 46 had cases of pellagra, or 8.7 per cent., a lower percentage than any other group. In 193 persons who did not use fresh meat at all, only 1 new case of pellagra was observed, an incidence of 0.50 per cent. He had been able to demonstrate the presence of amebæ in the centrifuged urine of about 50 per cent. of pellagrous cases that came under his observation, and about 40 per cent. showed a mild to a severe and marked pyuria. The amebæ were large and small, and one marked feature was that they were very sluggish in their movements. Sometimes a cell resembling an encysted ameba would have to be recognized and kept under close observation in order to observe motility, while some were very actively motile. While he had no evidence at hand to prove conclusively that amebic invasion *per se*, or with a proper symbiosis, was responsible for pellagra, the symptomatology, the clinical course, and the post-mortem finds as reported ran parallel with the depredations often observed in a profound amebic invasion.

Dr. ALLEN W. FREEMAN of Washington, D. C., said whether we believed pellagra was due exclusively to diet or not, he thought we agreed that the evidence was strong that there was a definite relationship in many cases between the incidence of pellagra and certain deficiencies in the diet. That there was a definite relationship in the incidence of pellagra between classes fed on different diets in institutions had been proven successfully by changing the diet; furthermore, pellagra had been produced experimentally by limiting the diet to certain elements in common use in the South. Dr. Goldberger did not claim, and did not pretend to prove, that diet was the only factor in pellagra, but he had produced something which, it seemed to him, we must either try out or reject. He had shown that he could produce pellagra so clean cut that we must either totally disprove his findings or attempt to put the régime he recommended into effect.

Dr. STEWART J. ROBERTS of Atlanta said there were two chapters in connection with pellagra that had not yet been written. First, the absolute proof of the cause of the disease. Of theories there had been many since man began to study the disease after Casal first described it. What was the one thing that we most needed in this country at the present time in regard to the etiology of pellagra? Absolute honesty in realizing that we did not know the cause of the disease because we could not prove it, and we had been too long in pellagra seeking after a sign. We had many signs. What we needed was one proof. The second chapter in pellagra that had not yet been written was the one as to the treatment of the disease. Coming to the cure of pellagra, let us understand one another clearly, and let us be absolutely honest. By the cure of the disease he understood that a patient who had had the disease remained absolutely free of it forever unless reinfected. He met good professional friends everywhere who told him they had cured 600 patients of pellagra. Another man said he had cured 200 patients. It was one thing for a pellagrin to recover from an attack of pellagra, but it was quite a different thing for a pellagrin to recover from the disease which we called pellagra. He was sorry, if he appeared to be blunt, but if as Americans we were ever to solve the problem of pellagra, it would be after we had come down from our mistaken confidence, after we had come down to absolute intellectual honesty, and finally worked out somewhere, sometime, proof.

Dr. O. M. MARCHMAN of Dallas, Tex., stated that since last August the City Society decided to hold a pellagra clinic and they had at that clinic some twenty-five or thirty patients in different stages of the disease. He found from reports from the different physicians of the county and surrounding counties that they had used every available remedy, and not only the patients at the clinic but others treated in the various institutions were relieved in a like manner by all of these various treatments with a liberal generous diet. They found upon investigations at the clinic and from reports that they had had probably 100 cases of pellagra in Dallas since last August, an increase of 100 per cent., from previous years. These pellagrins were from the poorest class and were fed a one-sided or limited diet. A great many of these patients were put upon a generous diet, without any medical treatment whatsoever, and recovered as rapidly as those put upon various gunshot prescriptions.

Dr. ALLAN EUSTIS of New Orleans said he had heard no evidence as yet to counteract Goldberger's ideas. He

did not believe any of us were able to pass on Goldberger's results until we saw the published details of his investigation. Personally, he had never seen Dr. Goldberger claim that he had found the cause and a cure for pellagra, but he believed the condition could be remedied in great part. Erythema was only one of the symptoms of pellagra, and he was anxious to see what were the other symptoms that these patients in Jackson, Miss., developed.

Dr. JOHN E. STINSON of Chickasha, Okla., believed pellagra was infectious, and it was one of the most dreadful maladies he had ever been called upon to treat. Take the symptoms of the disease as they manifested themselves, and they were hard to combat by any method of treatment. He did not believe any true case of pellagra had ever been cured.

Dr. JAMES A. HAYNE of Columbia, S. C., said that a person might make a mistake in the diagnosis of pellagra in children in mild attacks of it, but he did not make mistakes regarding the terminal symptoms of the disease, and when a physician wrote a death certificate that a patient had died of pellagra, that was probably the cause of death. In South Carolina up to the present time they had had 1200 deaths from pellagra. To give some idea of the difference between pellagra and typhoid fever, the death rate from typhoid fever in South Carolina was only 26 per 100,000. It was about equal to the death rate from the circulatory diseases, such as heart disease, kidney disease, and so on.

Dr. JOHN L. JELKS of Memphis, claimed that certain diets were very good, while others were very bad, in cases of infection of the gut, such as we had in pellagra. A patient from Dallas was supposed to have been injured on the Cotton Belt Railroad at Texarkana, was brought to Memphis, and \$500 offered by the claim agent as a settlement was refused; a diagnosis of pellagra was made, not from the skin manifestations, but from the gut. He depended more upon the contents of the gut than upon the skin manifestations which were one of the latest symptoms to develop, after which death was almost certain. Patients with amebiosis would manifest the same train of symptoms as those encountered in cases of pellagra. Note the number of cases of amebiosis in which there was pain in the back of the neck. Note the number of cases in pellagra in which you find pain in the back of the neck. Note the number of cases of pellagra in which you find marked melancholia. Nearly all of the cases had a blood picture to which one of the essayists had called our attention. He believed that pellagra was an infection which took place primarily in the gut.

Dr. J. R. LEHMANN of Dallas, Tex., stated that it had been shown that we carried in our mouths the organisms of pneumonia, and yet all of us did not get pneumonia. But when conditions were ripe, with lowering of the vital resistance, we developed pneumonia. Was it not possible that the cause of pellagra, like that of pneumonia, was lurking around seeking whom it might devour, and only when conditions existed which favored a lowering of the resistance did pellagra develop.

Dr. A. A. HEROLD of Shreveport, La., said he was converted to diet as the principal causative factor in pellagra, and he would tell briefly why: He was health officer of Catto Parish in Louisiana, and in that parish agricultural and mineral oil regions were side by side. There was practically no difference between the people who lived there. In the mineral oil districts sanitation was more imperfect; flies and mosquitoes were more numerous in the oil region, and insect-borne diseases, such as typhoid malaria, were much more common in the oil districts than in the agricultural, yet not one case of pellagra had been reported in the oil fields, but 200 cases had been reported from the agricultural regions. There was one explanation for that. The usual ration of the farmer was fat meat, cornmeal, and some syrup. On the other hand, the roughnecks in the oil regions would not stand for poor rations. They lived on a thoroughly mixed and varied diet and did not develop pellagra.

Dr. E. H. MARTIN of Hot Springs, Ark., believed that pellagra was infectious, and he agreed with Dr. Goldberger that a person who was well nourished would not contract the disease. It had been an axiom with him for several years that an absolute preventive of pellagra was a bank account. If a man had \$200 in the bank he was not likely to have pellagra. He had never seen a person during all these years, who had money in the bank, who contracted pellagra. A man who had money and who was well nourished would not

take pellagra, and the man who had pellagra, who got well nourished, would get well.

Dr. LEVINE of New Orleans stated that a study of the intestinal tract was the most important thing in making a diagnosis of pellagra. There was a class of cases of pellagra where the skin symptoms were lacking. Involvement of the nervous system was not present, and the only symptom was the involvement of the gastrointestinal tract. Patients would complain of stomach disturbance; they had symptoms of heaviness and fullness and pain, with slight cramps and loose bowels. The fact that pellagra was on the increase was due to the further fact that we were not sufficiently expert as yet to differentiate those cases which were pellagra from those which were not.

Dr. CHARLES W. GARRISON of Little Rock, Ark., said he would challenge the statement that the publication of the dietary treatment of pellagra was injurious to the people and the profession. In Arkansas they had a slogan, "Let Arkansas feed herself," and they were using pellagra to assist us in that movement. There had not been a single speaker, either representing the infectious or opposite theory of pellagra, who had not admitted that diet was one of the most essential and important factors in prevention and treatment of the disease.

Dr. FRANK H. CLARKE of Lexington, Ky., said that those who had the pleasure of visiting Lexington two years ago would recall the splendid agricultural district there. It was a short-horned and Jersey cattle country, a fine race horsing country, and a great many wealthy people had settled there, and yet pellagra had appeared among the rich as well as among the poor.

Dr. BRUCE recalled two patients who had returned from the Johns Hopkins, who were treated there for amebiosis with secondary anemia. These patients came under his observation during this year with the later symptoms of pellagra. The skin symptoms had shown up and the severe nervous symptoms. In the beginning these cases were incorrectly diagnosed and were treated as instances of amebic dysentery, and since then had developed all of the later symptoms of pellagra.

Dr. LOUIS LEROY of Memphis, wished to report in this connection an interesting case of pellagra which he had this spring, developing in an old woman who had at this time inoperable rectal cancer. Wherever one had a lesion in the intestinal mucosa, he had a possible port of entry for the subsequent development of pellagra. He had no respect for the statement that it was too early for anyone to get up and assure the people that there was no danger of contracting pellagra. One could name any one locality, and when one case occurred, if there were open earth closets, if there was ground infection, one could look for more cases pretty soon.

Dr. WILLIAM KRAUSS of Memphis stated that with reference to the open closet, until very recent times, they had no pellagra originating in the city of Memphis, but recently he had seen many cases of the disease which had originated there, and they had no open closets in our city. Something was said about personal cleanliness, and consequently one might infer from that that only people who were filthy in their habits contracted pellagra, and yet they had an increasing number of cases of the disease in Memphis among the best people who lived in the best surroundings, who took two baths a day, and ate good, nourishing food.

Dr. THOMPSON FRAZER of Asheville, N. C., said several years ago he saw a great many cases of pellagra, and he had heard so much had been written about it that he decided to look it up. He had overlooked a great many cases and had not recognized the disease; then he had a good many cases referred to him. He had seen from 75 to 100 cases of pellagra, but in the last two years he had seen but few, which he found was in keeping with the history of the disease which had tended to spread from one section to another.

Dr. C. B. BOWYER of Stonega, Va., said that for the benefit of those who made a study of pellagra, he would report the results of some observations they had made in the coal mining district. He had never seen a case of pellagra in a man who gave his occupation as that of a miner. He was talking with Dr. McCormack, and he said that pellagra, so far as he knew had never developed in miners in Kentucky.

Dr. W. L. ALLISON of Fort Worth, Tex., said when he came to this meeting he was opposed to Goldberger's theory, because he believed at that time he had made

the definite statement that pellagra was due to poor diet and that alone. He now agreed with him and believed as he did that diet stood as a predisposing factor. When one fed pellagrins good nourishing food lots of them got well, but it did not hold true in Texas that pellagra occurred only among the poor. The first trouble he had with the relatives of a pellagrin occurred about six years ago. A woman with pronounced symptoms of the disease died under his care, and the family came to see him about the nature of her trouble, and he told them she died of pellagra. They resented it very much. They wanted it distinctly understood that this woman was well fed. He had seen many cases of pellagra in people who were well fixed financially and who lived well. He did not believe the disease incidence could be explained by diet any more than tuberculosis and typhoid fever could.

Experimental Study of Quinine and Urea Injections in Hyperthyroidism.—Dr. LEIGH F. WATSON of Oklahoma City, said he had used quinine and urea injections for hyperthyroidism over 400 times and the results might be summarized in the following conclusions:

(1) The treatment is suggested only to relieve the symptoms of hyperthyroidism and is not recommended to remove the tumor in simple goiter. (2) The injection is a harmless procedure in experienced hands. It should be used only in a hospital by men skilled in goiter work. It is almost painless, and there is no post-injection discomfort. (3) Small infiltrations, frequently repeated, are to be preferred to massive ones. (4) If the injections are always made well within the thyroid, there will be no adhesions around the gland and operation will not be made more difficult because of the previous treatment. (5) The injection of a weak solution of quinine and urea has little effect, necrosis and connective tissue formation always occurring after the concentrated solutions are injected. (6) In treating toxic goiter the necessity of preventing pain from any injection, by the use of local anesthesia, is of vital importance. If acute attacks of hyperthyroidism are to be prevented, the use of preliminary injections into the most prominent portion of the goiter of a few minims of sterile salt solution, given at one to three day intervals, followed by injections of sterile water, will be found indispensable. The results of the quinine and urea injections depend on the amount of tissue destroyed. (7) The greatest field of usefulness for the injection will be found in those cases of beginning hyperthyroidism not severe enough to justify operative treatment, and as a preparatory measure to partial thyroidectomy in chronic cases of toxic goiter too ill to warrant any form of immediate operative procedure.

The Small Town—The Neglected Unit in Sanitary Administration.—Dr. A. W. FREEMAN of Washington, D. C., said that sanitarians had almost completely overlooked the small towns, the towns in the agricultural districts of the country ranging in population from a few scattering houses to one thousand people. Such towns were merely a group of country homes without the intervening farmland. The population was essentially rural and composed of people just one step removed from the farm. The fundamental sanitary needs of the small town were those of water supply and excreta disposal. The shallow well and the privy were condemned and attention was called to the usual appearance of both on the same building lot. It had been his observation that neither the well nor the privy were sufficiently protected. He deplored the aversion the average American had to paying taxes, and pointed out by a slight increase of taxes matters of sanitation could be easily taken care of and the public health protected. A public scavenger and the can privy should be advocated. Such privies were easily cleaned and the breeding of flies was kept down and public health protected. The cleaning of the can or vault privy could be made often enough to insure a high degree of sanitation. The work could be done for about thirty cents per month for a family. The great need of the south to-day was the improvement of the rural home.

Sanitation of the Rural Home.—Dr. R. N. WHITFIELD of Florence, Miss., stated that the rural home needed more improvement as a rule than any other home, because in the South the rural population was greatly in excess of that of the cities and towns, and, most of all, the public health services had been performed in the cities and towns to the exclusion of the rural districts. One exception had been made, and that was the work done by the Rockefeller Commission, which had been laboring five or six years in eleven of the South-

ern States. The second greatest need in the South was the divorcement of the public health from peanut politics. He condemned the pie-hunting and the coat-tail hangers-on for positions on public health boards and declared that no physician would be a success as a health officer if that physician was allowed to practice his profession. A full time health officer should be placed in charge of every county in the South, and he should be a capable and competent man.

Intensive Community Health Work.—Dr. JOHN A. FERRELL of New York stated that intensive community health work differed from ordinary health work in that a concrete health problem was taken and adhered to until measurable progress had been made. It was limited to a relatively small circumscribed area instead of being diffused throughout a large area, such as a state or a county. A detailed record of a survey was made of the area selected, including every home, school, church, road and stream, and usually the information was shown on a map. Every home was visited and inspected and every person examined as far as practicable with reference to the particular health problem under consideration. A record of the disease in the past and its probable consequences was made so that when the work began there was a definite starting point.

Rural Sanitation in the South.—Dr. J. HOWELL WAY of Waynesville, S. C., placed the chief responsibility on the one thousand three hundred and ten county governments of the Southern States for the improvement of conditions. He advocated the employment of a full time county health officer on scientific merits rather than on a political basis for the present. The chief difficulty in county work was the lack of a well defined plan of procedure, and he insisted that a rule of standards and model system would be worked out for counties soon. Eventually, when methods of rural sanitation became standardized, their counties grow in population as well, the unit system operated by state boards of health would naturally and appropriately give place to the whole time county health officer, but for the next five to fifteen years the unit system possibly was destined to exercise a more practical helpful influence on the progress of rural sanitation than could be involved by any adherence solely for the whole time county health officer plan, which so many counties did not feel they might institute as yet.

Immediate Necessity of Intensive Health Work in the South.—Dr. A. L. LINCUM of Austin, Tex., said that housing conditions were deplorable, especially among the tenants in the farming districts. The absence of screens on the doors, windows and porches of these homes cost annually for treatment of malaria more than the expense of screening would be.

Treatment of Suppurative Appendicitis.—Dr. SOUTHGATE LEIGH of Norfolk, Va., regretted the subject of suppurative appendicitis had not received the attention at past meetings of the Association that it deserved. While it was generally understood if properly handled by the profession, there was still room for great improvement and expansion of knowledge on the subject. While the mortality rate had been greatly reduced in appendicitis, it should be reduced even more. Great improvement could yet be made in the early handling of cases. As soon as a patient was suspected of being affected he should be placed upon a proper stretcher, the head of which was elevated, and in all cases the patient should be kept lying inclined to the right side that in case rupture of the pus sac took place the upper region of the abdominal cavity would be protected from the pus. The question of transportation of the patient was most important. The patient should be well propped up and kept inclined to the right side. Cathartics should never be given in acute cases. Delay in operating was often advisable, if the condition of the patient would permit, especially if the patient was fatigued from the journey and transportation. However, where all conditions were favorable, operating as soon as possible after the case had been properly diagnosed should be advocated.

The Use of Radium in Uterine Bleeding Due to Myometrial Degeneration.—Dr. C. JEFF MILLER of New Orleans stated that radium had proved a boon in inoperable cases of carcinoma, but he would not recommend it as the sole treatment in operable cases. The only treatment that promised relief from cancer was its early removal by surgery. He reported a number of cases in which he had used radium with beneficial and satisfactory results. He also asserted that radium, when properly screened, might be used as economically inside

the body of a patient as by being kept in a medicine case at the office.

A National Health Problem.—Dr. ARTHUR T. MCCORMACK of Bowling Green, Ky., delivered an address on this subject in which he brought a strong indictment against the United States Government for its failure to recognize the necessity of preserving the health of its citizenship. The present pure foods and drugs act was criticized. The speaker said that the enforcement of the law was so slow it made possible patent medicine fakes and really encouraged violations. He pleaded for prompt action in the department of chemistry and in the publishing of its findings at once. He advocated the correlation of the Bureau of Animal Industry with the Bureau of Health, saying that the health of animals and man were too closely intermingled to be separated. He wanted the Child's Welfare Bureau to be taken out of the Department of the Interior and placed in the Health Department. Research, education, leadership, organization, interstate and foreign and maritime quarantine, prompt statistics, as accurate as possible without being devitalized by delay, enforcement of Food and Drugs Acts, detailed solution of special problems of state and localities—but above all, leadership and study in methods of execution would be the beginning functions of such a federal department. The bringing together of all the health departments, even down to the municipal department, under the fountain head of the United States Health Department, was advocated. When such a time came he believed then diseases known to be preventable would be stamped out.

Malaria and Hookworm Disease.—Dr. W. S. LEATHERS of University, Miss., stated that either malaria or hookworm disease so devitalized the human body that typhoid and tuberculosis had but little trouble in completing the destruction. These diseases made the other diseases more deadly. The insidious diseases must be stamped out before any noticeable impression could be made upon the diseases having a higher degree of mortality. Public health depended almost entirely upon education, and when the people became educated along the lines of protection against the ravages of the insidious diseases, a great step in advance would be made. Teaching simple sanitation to the people was one of the great duties of public health departments. The Southern States reported for the year 1914 between two million and three million cases of chills and fever, and fifteen thousand deaths from malaria. The State of Mississippi reported 22,090 cases of chills and fever for the month of September, 1914. The land in the Mississippi Delta was being held down in price to-day because it was generally understood that living was almost impossible there. He could not understand why our government was spending millions to put water on lands in the West that would never be as productive as our lands of the South, and it would not give one cent to take the water off the land of the South. Our richest lands were those which became covered with water. Lands in the Mississippi Delta sold from \$20 to \$100 per acre when they should be selling for \$400 per acre. Malaria made living almost impossible in the Delta. This meant that millions of dollars were lost each year to the South due to this disease.

Immediate and After-Treatment of Railway Injuries.—Dr. W. W. GRANT of Denver stated that the importance and necessity of immediate first-aid treatment in such cases was apparent, by reason of the fact that these accidents were generally defined as contused, lacerated and mangled, and were much more prone to infection than smooth wounds. The application of iodine, peroxid of hydrogen and alcohol pending the transfer of the patient to a permanent place of treatment was common. Probing was seldom justified under any conditions. He spoke of the dangers of operating while the patient might still be suffering from shock of the accident, and declared that many surgeons did not realize the value of proper reaction before operating. To add a physical shock to physical injury would generally prove hurtful to the patient. There was no more urgent field for skilled surgery than the treatment of mangled feet, hands and fingers. Lacerated tissues were more liable to infection and healed more slowly than other wounds. The sewing up of torn and lacerated wounds was a sure harbinger of infection and would have to be opened up again. Drainage tubes constituted the safest plan for the prevention of infection. Scalp wounds were not generally attended by severe shock and healed rapidly, but the most insidious wound was the small punctured fracture.

Every such wound demanded early investigation or serious results would likely follow.

The Treatment of Malaria with Reference to Its Eradication.—Dr. T. E. WRIGHT of Monroe, La., said that in one of the hospitals used by the Missouri Pacific Railroad in north Louisiana 747 cases of malaria among the railroad men were treated during the years 1912, 1913 and 1914. During this year, beginning January 1, and ending November 1, 249 cases of malaria had been treated. The patients remained in the hospitals from four to six days. This short stay in the hospital was due to the intensive treatment given malaria cases in the hospital. This economic feature of intensive treatment and prompt results when applied to the whole malarial district of the South was a matter of much greater importance and should receive serious consideration on the part of medical men. The treatment used generally by him consisted of injecting quinin directly into the blood and the dose was generally ten grains. The doses were given every eight to ten hours. Intensive treatment of malarial patients must be employed in order to decrease the number of carriers. The intravenous use of quinin, administered with proper care, in doses of ten grains, in proper dilution, repeated in from eight to ten hours once or oftener, according to the case, was the type of intensive treatment that more nearly sterilized the blood of malaria than any other method heretofore employed. Fewer cases of recurrence would follow the intravenous use of quinin. The discomfort through this treatment of the patient was slight or of short duration, not lasting over five or six minutes. The technic was so simple that nurses in training might be taught to administer quinin by this method with reasonable certainty.

The Sex Question in Public Health.—Dr. ISADORE DYER of New Orleans said the sex question was essentially one of public health. Sex hygiene was to-day a fetish bandied about by the pedagogue, the preacher, the politician and the physician. Congress debated some phases of sex hygiene; both sides were vehement in urging and opposing the dissemination of knowledge among the young, and while they continued to disagree, the young go on learning in the old-fashioned way. Facts were needed in presentation of the sex question to young men and women, not preachments. He demanded in the future that the question be handled in an open and frank way with the children. He was of the opinion that perhaps the public school would be a good place to teach sex hygiene and he believed the proper men and women could be found to tell the children about the things that every child should know.

Dr. E. H. MARTIN of Hot Springs, Ark., favored separation of children in public schools, and said that segregation of sex was practiced in a Mississippi town in the public schools. Dr. Martin opposed co-education upon the grounds that a boy learning subservience to a woman was not liable to make a very good soldier in later years. He disagreed with Dr. Dyer in the handling of sex problems and did not believe it proper to recognize prostitution.

Dr. ALLAN W. FREEMAN of Washington, D. C., said he had been attending public health meetings for a number of years, but he had never heard a frank and honest discussion of the sex question. He agreed with Dr. Dyer that it was first a question of health and should be treated as such.

Syphilis, Its Relation to Public Health.—Dr. LLOYD THOMPSON of Hot Springs, Ark., advocated the registration of all affected persons and a heavy fine to be imposed upon the physician for failure to report. The marriage license should not be given to any one until he had been thoroughly examined and had withstood certain tests. He urged the adoption of a plan by employers to require a bill of health of every employee and to refuse employment to any person who would not submit to a physical examination. If prostitution was permitted, he believed it should be put under strict surveillance and regular medical examination.

Health Conservation Through Life-Insurance Companies.—Dr. J. L. DAVIS of Waco, Tex., stated that of all of the business propositions before the world to-day he believed the best one was to save human life. The life insurance companies had long ago realized this and had set themselves to the task of prolonging life. This they were doing by teaching their policy holders how to care for themselves and to give attention to little matters of health. The life insurance companies of the United States had taken the lead in matters of sanitation and right living. They had been advocating

Tuberculosis was recognized by insurance companies as an exceedingly infectious disease and for a great number of years they had made careful inquiries into the lives of applicants for insurance along this line. They had gone so far as to inquire whether the applicant had been associating with tuberculous people. Typhoid fever was characterized as the arch enemy of insurance companies. The next of the deadly enemies was alcohol, and the greatest temperance lectures of the age could be taken from the dry records of almost any life insurance company.

Sanitary Preparedness.—Dr. RUPERT BLUE, Surgeon-General, U. S. Public Health Service, said the maintenance of sanitary preparedness was no less the duty of the individual than it was of the community. The question that came then was how this end was to be accomplished. It was not altogether easy to reach so convincingly that the layman would appreciate these things. It must come in many ways. If upon the plastic mind of the school child the simple truths of sanitation were impressed, we gradually created a people in which sanitary living was a habit. If by child hygiene we produced better and stronger men and women, these in turn would bring into the world stronger children, because they would have learned that mating with the weak and defective produced weak and defective children. Thus we would have a practical eugenic betterment. He did not think it was necessary in this connection that he discuss the trite questions of the medical inspection of school children, the whole time health officer, diet, exercise and the other thousand and one things which we were practically of one mind. The impression he desired to leave in their minds was that, if America would avoid the decay and retrogression, if she would be ready for the supreme trial of strength when the hour of calamity came, she must retain her sanitary defenses at all times. The sane and healthy nation, republic of healthy minds in healthy bodies, adding by its labors, uninterrupted by disease, to the material and spiritual welfare of the world, was prepared alike for the piping times of peace and the stern realities of war.

National Board of Medical Examiners.—Dr. WILLIAM L. RODMAN of Philadelphia stated that the National Board would not in any way interfere with the State boards. All the National Board asked was that it would be treated with the same consideration, and that only, which was accorded to all of the several states. The examinations that would be required by the National Board would be of the same high standard as that of the highest state boards, and there was no reason why a licentiate of the National Board should not be recognized by the most exacting state boards. It was the patriotic duty of the several States to recognize the National Board because of the advantages to the government service. It was not a federal board under government control, but the government saw that it was a splendid thing to supplement it in time of war and pestilence. The examinations for a time would be held in Washington, but later they might also be held in the middle West and perhaps in the far East to accommodate practitioners all over the country. The standards would be high. First, the applicant must have had a four-year high school course. Second, he must have had one year at least in the elemental biological sciences. Third, he must have had four years in a high grade medical school and in addition at least one year of experience in a general hospital. The examination would be oral, written, laboratory work and clinical. Candidates would be required to make diagnoses, set fractured limbs, identify tissue under the microscope, and satisfy by a number of such tests his knowledge and ability.

Appeal for Military Preparedness.—Col. M. W. IRELAND, U. S. Army Medical Corps, presented the new policy of the medical departments of the Army and Navy for preparedness in keeping with the new military program of the national government. He said they were beginning the reorganization of the army which would increase materially the military establishment. They were working that the entire army might hold together in time of war without a breakdown. The Surgeon-General's office was seeking to provide the needed precautions to safeguard the troops. The Surgeon-General had asked for and secured the approval of the authorities of a plan that would allow seven medical officers for every one thousand men. If war came the medical departments of the Army and Navy must be greatly increased. In the past we had relied upon the National Guards, volunteers and the

Red Cross for this increase, but they were not sufficient for the medical department to perform its duty, as was shown by the experience of the Spanish-American War, when 21,000 cases of typhoid broke out in our concentration camps in the South and in our Santiago campaign. For the enormous work of war the medical department must have a great force of doctors, and they must be trained as medical officers in the army. The medical department failed in the Spanish-American War. In the 35 years of peace we had forgotten the lessons of the Civil War, and as a result thousands of soldiers suffered and died with typhoid fever. It was to guard against the recurrence of such a thing as this that the medical departments of the Army and the Navy were reorganizing and placing themselves upon an efficient preparedness basis.

The Allen Treatment of Diabetes by Fasting.—Dr. ISAAC IVAN LEMANN of New Orleans said it was the belief of Allen that we had been wrong in trying to maintain or increase the weight of our diabetic patients where glycosuria persisted, for such attempts simply kept the body at a size beyond the capacity of the pancreas to provide sufficient internal secretion for it. Better, therefore, to have the body thinner and have enough pancreatic secretion to do the work of a smaller body. This pancreatic internal secretion he would have us conceive as an amboceptor binding blood sugar to the tissues. When the amboceptor was lacking the unbound sugar was secreted by the kidneys. Allen's proposals were: (1) To starve the patient until his urine was sugar-free. (2) To add gradually to his diet until his point of tolerance of protein and fat, as well as of carbohydrate, was reached. (3) To remain within these points of tolerance, no matter how low they might be and no matter how thin the patient might be. Attempts to increase the patient's weight by the addition of a large number of fat calories to the diet results in the return of the glycosuria. His short experience with Allen's method embracing now five cases had served to free him of the fear of precipitating a severe acidosis by the sudden starvation, and, secondly, it had convinced him in one severe case of its great possibilities in certain cases at least. The other four cases were mild. In two of them he had tried in vain to stop a glycosuria by gradual reduction of carbohydrate intake, then of protein intake, and finally in one of them by the interposition of green days. These two patients became aglycosuric in twenty-four to forty-eight hours of starvation respectively. The other two mild cases required 24 to 72 hours starvation respectively. In none of these four did acetone appear in the urine. None of the patients had any serious complaints. Not only was the disappearance of the glycosuria brought about more promptly and with less trouble both to the patient and to him than by the former technique, but it was possible to build up for each of these patients quite a livable diet and still maintain them aglycosuric. In the two patients whose points of tolerance he had tried to determine by the older method, he found the new tolerance quite satisfactory and far in excess of what it had been prior to the past. His brief experience with the method had been sufficiently satisfactory and enlightening to encourage him to proceed.

Pyelitis in Infancy and Early Childhood.—Dr. L. R. DEBUYS of New Orleans stated that the majority of cases of pyelitis occurred under three years and of these most of them under two. In from 90 to 96 per cent. of the cases females were affected. It was highly probable that much of the trouble in the adult female kidney might have origin in the infections of the kidney during infancy and childhood. Pyelitis might be primary or it might be secondary to a cystitis. The treatment of pyelitis might be included under four heads: (1) Drugs. (2) Irrigation of the pelvis by direct method. (3) Irrigation of the pelvis by indirect method. (4) Vaccines. Many drugs had been advocated for use in pyelitis, among them urotropin, potassium citrate, methylene blue, creosote, and salol. Of these urotropin and potassium citrate were the most frequently used. Urotropin was best given early and in large doses, 2 to 3 grains, every three or four hours, to a child from one to two years of age. It was given for the antiseptic property of the formaldehyde liberated in the urine. The direct method of irrigating the pelvis of the kidney had been shown in the adult to be the most efficient means of combatting a pyelitis and its results were excellent. By far the most reliable method of treatment in pyelitis in the small patient was by irrigation of the pelvis of the kidney by

indirect method. By this was meant the giving of large quantities of liquids. It was well to dilute their food so that they might be always hungry, and in order to satisfy their hunger they must take large quantities of fluids to receive a sufficient quantity of nutriment. Vaccines were sometimes of benefit and should be autogenous. Their effect was not uniform and reliable, but in some instances had been of advantage. They should be given in doses beginning with 50,000,000 and increasing rapidly to 200,000,000 or even 250,000,000. The interval varies from three to five days, depending upon the reaction of the patient and the recovery from the reaction. In the resistant cases and the chronic ones the autogenous vaccine was more especially indicated. Should the vaccine not produce after from three to five vaccinations an immunity, as shown by the bactericidal property of the blood, its use should be discontinued.

Dietetic Treatment of Bronchial Asthma.—Dr. ALLAN EUSTIS of New Orleans stated that a review of 178 cases justified the following conclusions: (1) Most cases of bronchial asthma are due to absorption of proteolytic toxins. (2) These toxins may be absorbed from a suppurating accessory sinus in the nose or from the intestinal canal. (3) Treatment of intestinal toxemia is as important as any drainage of focal infections. (4) An alveolar abscess may be the focus from which the toxin is absorbed. (5) In the dietetic management of asthmatics animal proteins, with the exception of buttermilk, should be eliminated from the dietary as much as possible.

Influence of Potassium Iodide on Luetin Reaction.—Dr. RANDOLPH LYONS of New Orleans drew the following conclusions: (1) The experiments performed fully confirm the observations of Sherrick upon the influence of potassium iodide on the luetin reaction. (2) That iodine is the essential factor in producing the positive reaction in a non-luetin individual is demonstrated by the fact that hydriodic acid, thyroid extract, and possibly hyperthyroidism will produce a similar effect. (3) When a luetin test is made, it is essential that no iodine in any form be taken internally. Furthermore, it is important to know that iodine should have been ingested for an interval of at least three weeks previous to the performance of the test. (4) Torpid or later reactions occurring after an interval of two weeks are usually due to the ingestion of potassium iodide. The reaction may be influenced after an interval of two months by the subsequent administration of potassium iodide (Sherrick). Anomalous reactions may generally be attributed to potassium iodide. (5) Activation of the luetin test with mixed treatment vitiates it. (6) Clinical differentiation between the two, luetin reaction and iodine reaction, cannot be made with any degree of certainty. When a positive test develops very rapidly, an iodine reaction may be expected. (7) The extreme prevalence of the use of iodine in some form (potassium iodide) will necessitate a critical review of the published reports of positive reactions in order to eliminate the iodine reactions. This will undoubtedly lower the percentage of positive results.

A Plea for Uniformity in the Wassermann Reaction.—Dr. COURTNEY W. SHROPSHIRE and Dr. CHARLES WATTERSTON of Birmingham, Ala., said that from their experience and from their study of the literature, they came to the following conclusions: (1) That the results obtained with the Wassermann reaction and its modifications are subject to wide variation. (2) That this variation is due to modification in technique and to faulty technique. (3) That the members of the medical profession, judging by the reports taken from the literature, request some representative medical organization to take up the work of standardization, and place the reaction on a firm basis with definite units of strength and volume, and standard readings to be used by all serologists.

Artificial Pneumothorax.—Dr. JOHN J. LLOYD of Catawba Sanatorium, Va., drew the following conclusions: (1) The selection of cases should be carefully made if success is to be expected and the operation be saved from disrepute. (2) In spite of careful examination, including x-ray examination in some cases, we are unable to discover an extensively adherent pleura in a large per cent. of cases prior to attempting compression. (3) In the early part of the treatment all the cases should be treated as bed patients. (4) In order to accomplish the greatest benefit, the lung must be kept completely compressed for a long period of time—how long we are not yet in a position to de-

termine. (5) The immediate dangers are relatively slight and may be avoided by proper technique. The remote dangers are chiefly due to embarrassment of the better lung and may often be anticipated and prevented. (6) Artificial pneumothorax offers a chance for great improvement in a class of cases hitherto regarded as very doubtful.

Focal Infections.—Drs. W. C. MAYES, W. WILSON, and C. F. WILSON of Memphis, from their limited experience, drew the following conclusions: (1) That many diseases, the etiology of which has been obscure, are undoubtedly due to metastasis or absorption of toxins from a primary focal infection. (2) We do not believe that we have done our whole duty to a patient by simply treating the results of a metastatic infection or the symptoms of toxic absorption. (3) It is absolutely essential to remove the primary focus when possible or at least overcome the infection in the same in order to conserve the best body economy. (4) That in the diseases due to focal infection, if a cure is not effected by the removal of a diseased focus, or if further metastasis occurs, the focus removed was not the causative or only causative focus, and a further search should be made with a view to its removal or cure. (5) That if the focus cannot be removed, or the infection in the same controlled, for anatomical reasons, often the removal of a diseased tonsil, draining an apical dental abscess, or accessory nasal sinuses will allow the body economy to so recuperate that a cure will occur in the original offending focus. (6) That an innocent appearing tonsil may be the focus, and that the search for the offending focus is not complete without exhausting every aid of the laboratory, x-ray, and our own diagnostic ability.

Influence of the Injection of Blood on Anemia and Infections in Children.—Dr. J. SPENCER DAVIS of Dallas, Tex., said that in the injection of whole blood we had the therapeutic means of increasing the white blood corpuscles, that in many cases a crisis in the disease could be brought on, and that the destruction of bacteria in the body was hastened. He had found it of great value in the acute infectious diseases of children, such as scarlet fever. Like all other therapeutic measures, it sometimes failed where it was most needed, and its value was dependent upon the ability of the individual to respond to the injection. He had never seen any bad results following the injection, although at the site of the injection he had the same series of color changes which occurred in an ordinary bruise.

Scurvy Versus Rheumatism.—Dr. DANDRIDGE P. WEST of New Orleans stated that the prognosis of scurvy depended upon the early recognition of the disease, severity of the symptoms, and the complications. Death in untreated cases resulted usually from hemorrhage, exhaustion, and bronchopneumonia. In recognized cases, the treatment was highly satisfactory, and none was more easily instituted. It might be covered briefly by the rule: Discontinue all previous feedings, especially if they have been patented, boiled, or sterilized; give fresh milk, fruit juices, and if the digestion would stand it puree of potato or green vegetables. In all suspected cases the effect of the treatment, the therapeutic test, was of the greatest value, inasmuch as the results showed in forty-eight hours, and no harm, as a rule, could be done by waiting so long. If in doubt, when the baby was unduly irritable on being handled, and showed perhaps local manifestations of joint pain, preclude first the idea of rheumatism, change the diet to raw milk, and give orange juice.

Bronchial Gland Tuberculosis.—Dr. MARY E. LAPHAM of Highlands, N. C., said that in a very healthy hill district, where there had not been a death from tuberculosis in ten years, Hillenberg found that from 25 to 50 per cent. of the children gave positive reactions to tuberculin. A large percentage of their school children gave these same positive reactions and in the majority of cases no tuberculous foci were found. It was thought that the residence of tubercle bacilli in the bronchial glands accounted for these reactions and for the absence of demonstrable foci of infection. The presence of tubercle bacilli did not necessarily mean the development of tuberculous processes. It had been shown by autopsies that the bronchial glands were exceedingly oftenest infected, but that there were times when the tissues were simply swarming with tubercle bacilli, and yet there was not the slightest trace of structural changes even under the microscope. From birth to puberty bronchial gland tuberculosis might dominate the clinical picture, but after puberty we

must admit tuberculosis. Given sufficient time, the tuberculous processes in the bronchial glands of children might extend into the lungs and create the pulmonary tuberculosis of adults. A thorough comprehension of the tuberculous processes in the glands of children with all their possibilities of danger from adults, taught us the importance of discovering and arresting them at the very start. The tuberculosis expert knew full well that healthy school children were in far greater danger from the unsuspected extension of tuberculous processes than the sick ones were because bad health stimulated examinations and good health prevented them.

Common Sense and the Fever Thermometer Versus the Stethoscope and the Microscope in the Diagnosis of Early Pulmonary Tuberculosis.—Dr. S. E. THOMPSON of Carlsbad, Tex., said that in his paper he endeavored to prove the following points: (1) We were finding only a very small per cent. of our incipient tuberculosis patients. (2) That this was due largely to faulty teaching. (3) That as a result of this faulty teaching we could not rely on the stethoscope. (4) That the microscope would not make a sufficiently early diagnosis. (5) That in using common sense and the fever thermometer we could find a large number of early cases. Our attitude toward tuberculosis should be one of eternal suspicion. The white plague was everywhere. It was the most common, the most frequent of all diseases. The finding of our early cases was the general practitioner's burden, and if he would depend less upon the stethoscope and microscope and rely more on competence and the fever thermometer, he would find a much higher per cent. of his early cases and thousands of lives would be saved annually.

Rest and Exercise in Tuberculosis.—Dr. THOMPSON FRAZER of Asheville, N. C., said that in his paper he summarized briefly the chief points as follows: (1) A thorough knowledge of the principles of rest and exercise must underlie the treatment of tuberculosis. (2) Neither exercise nor rest was to be prescribed offhand, but so long as there were symptoms pointing to an overworked body rest was indicated, the character and amount to be carefully prescribed, and that with improvement exercise slowly increased provided the safest means of regaining health and strength. (3) Exercise must be very gradually increased as a single act of over-exertion might delay the recovery months, years, or even make it impossible to attain. (4) The transitional period referred to should be continued under careful medical supervision until the patient was able to stand without harm more than he would be called upon to stand when he took up active work. If these points were duly considered, and, if instead of vaguely advising rest or exercise we limited the amount and character of each to the age of returning our patients to a condition in which they would be able to successfully cope with their changed environment, in the future we should hear less and less of relapses and should be able to accomplish what should be our chief aim—an economic cure.

The Recognition and Treatment of Occult Tuberculosis.—Dr. SYLVIO VON RUCK of Asheville, N. C., said that in many cases the diagnosis of an obscure clinical condition depended upon what happened to enter the physician's mind as possibly standing in relation. If it was kept in mind that tuberculous infection was practically universal, that the majority of persons possessed a fair resistance which, however, might be broken down temporarily or permanently by many factors; that tuberculous disease might be latent in the sense that it presented no symptoms at all, or that the symptoms might be atypical and that the obscure cause of certain clinical manifestations might be a specific toxemia, it became evident that the idea of such a toxemia having a tuberculous origin was not far fetched. It was characteristic of many conditions, and this would aid in the appreciation of their true nature, that they resisted the modes of treatment which were ordinarily effective, as was pointed out in the case of pseudochlorosis by Trousseau, and as was insisted upon by many authors in the case of tuberculous rheumatism, in which the salicylates were useless. In cases, therefore, in which the ordinary indicated remedies remained without effect, it would be proper to keep the possibility of a tuberculous intoxication in mind and at least to make a diagnostic tuberculin test which should be subcutaneous, or still better made with the vaccine, because this preparation would at the same time exert its therapeutic effect. In accordance with the old truism that the cures of diseases demonstrated

their nature, it was in this manner that an obscure clinical condition could be established, and that simultaneously a curative remedy was introduced which would exert its beneficial action in those cases in which a tuberculous intoxication or an occult tuberculous process stood in relation to the clinical symptoms.

Therapeutic Hints.

Weeping Eczema.—Unna says the simplest method of treating moist eczema is to coat it often with a thin layer of some drying paste. This does away with the necessity for dressings and the microorganisms die when excluded from the air. The thinner the layer and the oftener it is applied the better. As the germs are killed the itching subsides. The formula he advises is a mixture of 10 parts sulphur lotion, 10 parts calcium carbonate, and 80 parts zinc ointment. This paste is also useful to apply to a vaccination pustule as soon as the vaccine shows that it is going to "take." The course of the pustule is not interfered with, but there is no redness or swelling and the whole process is shortened.—*Berliner klinische Wochenschrift*.

Ingrowing Toenail.—

R Acidi hydrochlorici, ℥xxii.

Glyceriti pepsini (N.F.), ʒss.

M. et signa: Apply on lint to the affected toe, covering the entire nail and its valla.

Hemorrhoids.—

R Potassii iodidi, gr. iij.

Pulveris opii, gr. v.

Pulveris camphoræ, gr. x.

Acidi tannici, ʒii.

Adipis lanæ hydrosi,

Petrolati, āā ʒss.

M. et signa: Apply on lint.

Amenorrhea.—

R Extracti aloes, ʒss.

Ferri sulphatis exsiccati, ʒi.

Asafœtidæ, ʒij.

M. et ft. pil. No. 50. Signa: One or two pills after each meal.

Paraffin Oil Emulsion.—Dr. Eric Pritchard, who claims to have been the first to use liquid paraffin in the treatment of constipation, administers it by preference in the form of an emulsion, known as the "Marylebone petroleum emulsion," of which the following is the formula:

R Paraffin liquidi, B.P., 33.0.

Acidi benzoici,

Glusidi (saccharin) āā 0.05.

Olei cinnamomi, 0.10.

Decocti chondri crispi (Irish moss), q.s. ad 100.0.

The dose of this emulsion is nearly three times that of the pure oil.

Calcium lactate has been found by White to give excellent results in many varieties of skin diseases, including urticaria, erythema multiforme, pernio, and hyperhidrosis. He recommends the following formula:

R Calcii lactatis, gr. clx., 10.0 grams.

Tinct. capsici, ℥. viii, 0.5 c.c.

Aq. chloroformi, ʒxx, 500.0 c.c.

Solve et misce. Sig.—Two tablespoonfuls (25 c.c.) in water before meals.—*Journal of Cutaneous Diseases*.

Acne.—Make a paste containing beta-naphthol, gr. 1; precipitated sulphur, ʒss.; lanolin and green soap, of each ʒii. Cover the affected portions of the skin with a thin layer of this paste for 20 minutes; then wipe off the skin and dust with talcum.—Lassar.

CONSULTING LARYNGOLOGIST TO ST. LUKE'S HOSPITAL

THE HISTORY OF TONSILLOTOMY.

WHILE the records of neither Assyria, Babylonia, nor Egypt appear to contain reference to this subject, the recognition of diseased conditions of the tonsils and the surgical treatment of the gland when enlarged must have existed from a very early period. Coming more and more into popularity during recent generations, few operations have been so frequently performed, with a greater measure of benefit to the patient, and, until recently, with less advancement in the positive scientific knowledge of the surgeon.

Theories innumerable as to the physiology and pathology of the tonsil have been advanced, and countless methods proposed for its treatment when diseased. Much controversy has therefore arisen regarding it, which, far from having been settled in our time by well-organized scientific investigation, still continues to hinder progress and to vex the professional mind.

Without question the urgent present needs in this department are, a clearer knowledge of the physiological value of the tonsil, recognition of the necessity for accurate diagnosis of its diseased conditions based upon recognized pathological principles, and, finally the practical, scientific testing of promising methods of treatment, the careful comparison of the relative values of these methods as observed in large numbers of operated cases, and, finally, the long-continued study upon the individual of end results.

Of the various methods employed in recent years, radical extirpation of the tonsil by so-called enucleation has been heralded as the latest improvement, and has gained many advocates. Strange to say, the first mention extant made in recorded history of any surgical method for the removal of the tonsils refers to this very expedient; for Celsus, writing in the year 10 A. D., nearly twenty centuries ago, says: "Tonsils which remain indurated after inflammation, if covered by a thin membrane, should be loosened by working the finger around them and then torn out. But when this is not

practicable, they should be seized with a hook and excised with a scalpel."

Aetius, no less than 500 years later, the next whose writings have brought us mention of the subject, assumes a position of far greater caution than did Celsus. He advises that the portion of the tonsil which projects, namely about one-half of the entire gland, may be removed; and he emphasizes the fact that "those who extirpate the entire tonsil remove at the same time structures which are perfectly healthy, and in this way also give rise to serious hemorrhage."

While Aetius could not have recognized the full import of his objection to the complete removal of healthy tonsillar tissue, he seems to have been the first to sound the warning against it which at the present time is claiming so much serious and intelligent attention; and thus at the very outset to have inaugurated the discussion upon "Tonsillotomy versus Tonsillectomy," a controversy which having flourished for 1500 years is still maintained with ever-increasing vigor.

In the ages following the time of Aetius, the interest of the profession in the subject waxed and waned, sometimes seeming to have altogether expired, and again being revived with more or less energy. But always the knowledge was vague, and the differences of opinion numerous and unreconciled.

Dionis, writing in 1672, opposed the removal of the tonsils because of his belief in their physiological importance.

As late as 1809, William Cooper of London, in his Dictionary of Practical Surgery, describes the various methods of operation then in vogue, and says that the most popular were the knife, the scissors and the ligature. His article ends with the statement that "the best modern practitioners for this operation prefer the common knife to any other instrument." During the twenty years following this statement of Cooper, interest in the subject became active in the United States. Several attempts were made here to improve the conditions of operation, and in particular to devise some satisfactory means by which the application of the silk ligature or the wire loop to the base of the tonsil to be ablated might be facilitated.

Much attention seems to have been awakened to the subject, especially in Philadelphia, Physick and Smith of that city, and Alexander Stevens of New York, devising instruments of considerable ingenuity, generally of the ecraseur type. None of these, however, long survived.

In 1828, Physick gave to the world the invention which was destined to revolutionize the practice of the time, an instrument which has probably been more widely accepted, more extensively modified and more persistently utilized than any other contribution to practical surgery of the century. Perfected by the genius of Sir Morell Mackenzie,

for many years it ranked without a successful rival; and to-day, as the so-called "Sluder modification," again heads the list in popular favor.

In 1832, Dr. W. B. Fahnstock of Lancaster, Pa., published a description of a ring-knife tonsillotomy in which, contrary to that of Physick, the action of the cutting edge of the instrument was from behind forwards. This device was soon taken up by various instrument makers, especially in Continental Europe, the best known and most effective of its countless modifications being that of Matthieu, of Paris.

It is an interesting fact that the models of Physick and Fahnstock, made in this country at nearly the same time, have dominated the entire world of laryngology for nearly a century. Meanwhile, following them other workers were not idle. Time after time the discussion upon the removal of the tonsil was revived, perhaps nowhere more vigorously than in New York City under the influence of Dr. Horace Green, who in 1845-65 founded the science of laryngology and incidentally taught his generation the value of tonsillotomy, operating after the manner of Louis of Paris with a bistoury or with scissors aided by a sharp-toothed holding forceps.

The prevalence of hypertrophied conditions of the tonsils of late years has been calling attention to this subject more than ever; while the method of operating under general anesthesia, inaugurated by Sir Morell Mackenzie about thirty years ago, and the still later discovery of local anesthesia, have opened the way for practically all of our modern improvements, and have enabled work of a thorough and satisfactory character to be performed. Strange to say, this seems to be the only feature of importance in this connection suggested outside of the United States.

As from the beginning, however, opinions relating to the general subject of the tonsil vary, discussion is active, and there is still much to be learned.

By far the most important question now at issue is that of diagnosis, for a clear distinction must be made between glands which are enlarged merely from temporary conditions of congestion, and those which are chronically hypertrophied and radically diseased. If, as many with good reason believe, the physiological function of the tonsil is a matter of serious importance in the general economy of nature, and, therefore, the organ should not be unnecessarily destroyed, especially at a time of life when its presence may be most needed as a factor in the normal development of the child, too great care cannot be taken to differentiate between cases demanding removal and those in which a proper course of treatment would effect a cure. Many of our clinicians would do well to acquaint themselves with the warning of Dr. John Noland Mackenzie, of the Johns Hopkins Medical School, against this crying evil, and to reconsider the dictum that every tonsil, from whatever cause enlarged, should be at once completely extirpated. Fortunately efforts are being made by Dr. Thomas R. French of Brooklyn, and in various other parts of this country, to improve the general knowledge of the subject and to evolve a perfect system of diagnosis and treatment.

This we also are trying to do at St. Luke's Hospital, where all patients are carefully examined as to the necessity for the removal of the tonsils before operation is advised, and where, through the liberal-

ity of the management, patients operated upon at the clinic are provided with beds until such time as they may be safely dismissed. Under the able supervision of the Associate Attending Surgeon a method of operation has been developed which appears worthy of attention. A description of it by him follows.

THE REMOVAL OF DISEASED TONSILS.*

When in January, 1912, the Clinic of the Department of Laryngology and Rhinology of the Out Patient Department at St. Luke's Hospital was

FIG. 1.—The submerged tonsils; Jennings mouth gag; electric illumination thrown from the angles of the mouth

formally opened the most important problem presented was the disposition of the many cases of diseased tonsils and adenoids which presented themselves. The Director of the Clinic had long

FIG. 2.—Left tonsil raised out of its bed (with the Beck instrument) before engaging; showing also the Titus tongue

believed and taught that the proper care of such patients after operation was an important feature of their treatment and that the custom of dis-

*Read at the meeting of the Laryngological Section of the New York Academy of Medicine, Oct. 27, 1915.

missing them at once from the Clinic and allowing them to return to their homes was unscientific and dangerous. He considered this especially true of those operated upon under general anesthesia. The superintendent of the hospital recognizing the wis-

der general anesthesia, and that of Justus Matthews in local tonsillectomies.

Without criticism of other methods, in our hands the Beck instrument gives most satisfaction in the majority of cases, under anesthesia. The technique

FIG. 3. Right tonsil engaged in the Beck instrument

dom of this persuaded the Board of Directors to open a ward of seven beds in the Out Patient Department for the accommodation of children under twelve years of age. With this nucleus the operative work was begun. In November, 1914, the service was still further benefited by the opening of a male ward and a female ward in the main building of the hospital to adults and to children over twelve years of age.

Efforts were at once made to improve the technique of the operative work of the clinic. Tonsillectomy having taken the place of the old time tonsillotomy in cases requiring the thorough removal of the gland, our operations were begun by

FIG. 4.—Both tonsils engaged in the Beck instruments.

blunt dissection and then enucleation with the Mosley snare. As time went on other snares were used, but gradually the operative procedure followed the methods of Sluder and Beck in operations un-

FIG. 5.—Both tonsils engaged, tenaculum applied

of the procedure which we have developed may be described as follows:

The patient is anesthetized with gas-ether anesthesia until the secondary stage is reached, and draped for operation in the usual manner. Lying prone on the table, without a pillow, the Denhart, Jennings, Whitehead, or Murdoch mouth gag (depending on the formation or condition of the teeth) is introduced, opening the mouth to its full capacity, and is held in place by the anesthetist; the chin slightly elevated to allow free breathing. The Titus suction tongue depressor is then introduced and the throat cleared of mucus. The advantage of this instrument is that it avoids injury to the mucous membranes and dispenses with unnecessary bleeding caused by the use of gauze or cotton sponges.

FIG. 6.—The tenaculum with enucleated tonsils.

With the right hand a Beck snare is introduced from the left angle of the mouth, the loop passing posterior to the right tonsil. The tonsil is then forced through the loop, the catch is sprung and the

snare wire drawn tight and locked. Two or three turns of the screw insure the engagement of the snare, which is now handed over to the assistant. In like manner the left tonsil is forced through the loop of a second Beck instrument and engaged,

FIG. 7.—The pharynx after operation.

the manipulation of the instrument being with the left hand. This snare is also placed in the hand of the assistant.

The assistant then gently raises the snares, thus approximating the tonsils in the median line; the operator applies a tenaculum to both tonsils at the same time. The assistant takes one instrument, the operator the other and slowly the tonsils are enucleated, the assistant removing the tenaculum holding both tonsils.

What little bleeding follows the operation is usually controlled by gentle pressure, by placing vaseline coated gauze pledgets, held on sponge sticks, between the pillars. Hemorrhage seldom occurs if this method is adhered to.

This operation has many advantages. Aside from

FIG. 8.—The tonsils.

the small quantity of blood lost there is no method that leaves so little traumatism; the uvula is never sacrificed or bruised and the pillars are left intact. Pain following the operation is minimized, the

slough quickly disappears and healing occurs in a very few days, leaving perfect anterior and posterior pillars.

The linear scar so frequently met with after tonsil operations, showing adhesion between the styloglossus and stylopharyngeus muscles is never present.

The after-treatment is of the simplest kind: children are seldom detained longer than twenty-four hours and are dismissed with the admonition to gargle or wash their mouths with cold or warm water according to preference and advised to chew flavored gum for a few days, the threefold object being to get rid of the unpleasant after taste of anesthesia and of sloughing tissue and to exercise their jaws.

In adult patients when general anesthesia is not advisable local tonsillectomy is performed as follows:

The patient is given Magendie solution, $m\bar{v}$ vii, with atropine sulphate gr. 1/150, an hour prior to operation and kept quietly in bed until wheeled into the operating room; then seated in a chair and draped. The mucous membrane of the mouth and pharynx is painted several times with a 10 per cent. solution of cocaine and after an interval of ten minutes the tongue is depressed and a $\frac{1}{2}$ per cent. solution of novocaine is injected into the anterior and posterior pillars, parallel to and $\frac{1}{8}$ inch from the free border. After an interval of one minute and with the tongue depressor again in position, using the Robertson curved tonsil knife (sharp on both edges and dull at the point), an incision is made beginning at the lowest point of the anterior pillar and with a quick movement of the hand carrying the incision upward to the angle between the pillars then, sweeping downward behind the tonsil and between it and the posterior pillar, using the other edge of the knife, to a point opposite the place of beginning. The left tonsil is firmly grasped with a tenaculum at the highest possible point, gentle traction made on it with the left hand, and the tonsil separated from its bed by the knife, in the right hand, making pressure first against the stylopharyngeus muscle, then the lateral constrictors and, finally, the anterior pillar. A snare is then used to free it from its lower point of attachment. The patient is quickly given an iced saline mouth wash, which is usually sufficient to control bleeding, after which the right tonsil is similarly removed.

The patients as a rule complain of little pain except during the separation of the tonsil from its bed, when traction is made upon it.

The after treatment consists of an ice bag to the angles of the jaw, the length of time suiting the patient's pleasure; a gargle of alkaline saline solution; orthoform tablets gr. v dissolved on the tongue ad libitum, and codeine gr. $\frac{1}{4}$ to control pain if present. The latter is repeated until comparative comfort is obtained. The following day several local applications of glycerite of tannin are made to the raw surfaces, the slough disappearing in from two days to a week, depending on the size of the wound.

The results obtained by these methods after a year's trial are encouraging and seem to warrant a continuance of them.

I wish to express here my thanks to Dr. Arthur B. Eisenbrey for the photographs and to Dr. Thomas R. French for his kindness in retouching same.

FRACTURES OF THE ELBOW.

BY JACOB GROSSMAN, M.D.,

NEW YORK.

ORTHOPEDIST TO LEBANON HOSPITAL, O.P.D.

THIS paper is based on the study of fifty cases of fracture of the elbow, which were treated by the acute flexion position and in which we have succeeded in obtaining good functioning limbs in some and a cure, with normal functioning limbs, in the majority.

Some of these cases were not diagnosed before coming to our clinic; these were treated as sprains, twisted tendons, and contusions of the elbow. There were two cases in this series, in which the fragments were not properly reduced, resulting in an almost complete ankylosis of the elbow. This necessitated prolonged, painful after treatment, which was usually avoidable, as our series had taught us. At this date, almost three months after the injury, there is still present limitation of flexion and extension, which we doubt will ever be entirely overcome.

Most of the cases treated by the acute flexion position, with early massage, passive movements and exercises, have recovered as near the normal with good functioning limbs within three to four weeks' time.

The majority of the cases occurred in childhood. In children the elbow is a center of traumatism because it is a point of diminished resistance. The lower end of the humerus is in the process of development and ossification and is unprepared to offer resistance to an unusual strain. In the cases where the children fall upon the outstretched palm of the hand, the shock is transmitted from the ground to the shoulder and is centered at the elbow, especially upon the lower extremity of the humerus and the articular end is not only broken but the fragment usually dislocated. This is particularly so in supracondyloid fractures. The elbow is usually swollen and ecchymotic and manipulation is extremely painful. In supracondyloid fractures the ecchymosis usually surrounds the elbow and in fractures of the condyles it is localized at the sides.

Where the condyles and the olecranon process are intact and their normal anatomical relations are not disturbed, one usually suspects a supracondyloid fracture. In the normal elbow, when the forearm is fully extended the tip of the olecranon and the condyles lie on the same transverse line and any modification of this normal relation of the three bony points is due to fracture or dislocation.

In supracondyloid fractures we find that the tip of the olecranon process is pulled backwards and upwards, but it maintains its relative position, *i.e.* a straight transverse line with the epicondyles. There is fulness in front of the elbow caused by the overriding fragments, which produces a deformity that simulates backward dislocation of the elbow joint.

It is very important not only to make a clinical diagnosis of fracture about the elbow, but also to confirm it by means of the Roentgen ray. After the diagnosis is confirmed, the reduction made and the dressing applied a second Roentgen ray picture should confirm the accuracy of the results.

With the exception of those cases of fractures of the elbow primarily irreducible, such as those rare cases of impaction, or the interposition of the fragments in the joint where the interarticular obstacle opposes reposition, a good prognosis can

be given. These cases left to themselves inevitably produce unsatisfactory results; they must be relieved by surgical intervention.

There are other cases which present certain difficulties in reduction even after the clinical diagnosis and the Roentgen Ray have confirmed the findings and reduction seems simple. Such cases are those with very small fragments and tremendous swelling, such as interarticular fracture of the condyle or fracture of the neck of the radius. The fragments are so small that the fingers can secure little hold, especially in the presence of much swelling. Many of these cases escape unreduced and result in defective consolidation.

One must always have in mind the importance of proper retention of the fragments after reduction. The fragments have a remarkable tendency to secondary displacement after reduction. We have found in this series of fifty cases, the acutely flexed position of the arm best adapted for maintaining reduction in this variety of cases.

Our fifty cases were divided as follows: Internal condyle, 24; external condyle, 14; supracondyloid, 8; olecranon, 4.

Supracondyloid Fractures.—This fracture is fairly common. It runs across the humerus just above the joint; the line of fracture may be irregular and very often is oblique. The forearm and elbow are carried upward and backward and the lower fragment goes with them so that the lower end of the upper fragment lies in front of the elbow. The lower fragment is also bent somewhat forward. It is very important to reduce the deformity as the movements of the elbow joint are greatly interfered with. In our series of cases there was practically no loss of flexion or extension.

Treatment: Reduction.—Where possible an anesthetic should be used. Flex the elbow to a right angle and then make extension with one hand, while the fragments are manipulated into position with the other. If kept in this position the recurrence of the deformity is very apt to occur. Acute flexion is the only one that is likely to maintain the fragments in good position. Supinate the forearm fully and flex the elbow as far as it will go. This will bring the point of the elbow forward and will push the lower end of the upper fragment backwards. This flexed position is maintained by means of a flannel bandage; it is of especial value in children.

The bandage is applied as follows: when the fracture has been reduced the bare arm is fully flexed so that the hand on the affected side rests on the opposite shoulder and the elbow is carried well forward on the chest. In the majority of cases this position retains the fragments in proper position. The forearm is now bandaged to the arm by figure of eight turns (see Fig. 1). Before applying the bandage the arm should be dried and powdered and a piece of boric acid lint placed in the elbow crease and axilla to absorb the perspiration and keep the parts dry. The limb is kept in position by a sling about the neck. It is very desirable, if possible, to take an *x*-ray picture to see if the fragments are in good position. Should the *x*-ray show bad position the dressing should be removed and the deformity corrected.

At the end of a week or ten days the bandage is removed and careful passive movement is begun. In performing passive movements grasp the elbow with one hand and flex, extend, pronate and supinate the forearm to its full extent. This should be done

once only at first and repeated three times a week. Massage once or twice daily can be given. On account of adhesions and callus usually a long period of massage is required. The acuteness of flexion is now gradually diminished by lengthening the sling. Flexion must be maintained for at least three weeks. The object of this is to prevent the formation of callus in the coronoid fossa. Callus may form in the olecranon fossa and lead to some limitation of extension, but this is of less importance than limitation of flexion. An arm that can be moved from full flexion to a little beyond the right angle is a serviceable limb, whereas movement from full extension up to a right angle means a comparatively useless one. If the limb can be used voluntary movements in the form of exercises should be encouraged as they will increase the range of movement, but where the limb is not serviceable the full extent of movement may never be regained.

Exercises.—The following exercises have been tried in our cases and have proven very satisfactory.

1. (a) The patient stands straight, heels together, head straight, arms extended by the sides of the body, palms being inwards. (b) The arms are brought straight out, forming a cross with the body. (c) Then by the side of the head touching the ears and as straight as possible. (d) Return in the same manner to the position of rest.

2. The same position as above, (a) start movements from the following position: the elbows close to the side, forearm bent upon the arm, fists closed, with the thumb side to the shoulder. (b) Then the length of the body. (c) Then in a cross. (d) Then vertically upward by the side of the head, touching the ears, and as straight as possible.

3. The palms upwards, the arm describes a half circle, to rejoin at the sides of the head; there the fingers cross each other, the patient stretches out as far as possible and brings the arms back parallel to the side of the body by describing a half circle in a vertical plane.

4. The head straight, arms extended at the sides of the head, bend the trunk forward at the hips so that the fingers, united by their palmar surfaces, touch the ground; return to the previous attitude with the arms in the same position.

5. The patient standing opposite a wall and an arm's length from it, stretches out the arms horizontally in front and applies the hands flat against the wall; without moving his feet the patient slowly approaches his body to the wall by bending the arms on the forearms, then he slowly recovers.

6. The patient stands straight, feet together, head straight, a rod or stick about 4 feet long is then grasped firmly by the hands about 2 inches or more from the ends and raised above the head, the hands still remaining the same distance from the ends. The rod is next lowered behind the back as far as possible. The hands must still retain their position on the rod, but the elbows must be bent. Alternately raise and lower the rod.

The efficacy of these exercises can be increased by the use of dumbbells and also with a Dowd's machine. They should be practised daily and not long enough to exhaust the patient.

CASE I.—Anthony D., six years of age. Fell and struck on his left elbow. He complained of severe pain and disability in the injured limb. Examination showed that the elbow was held in flexion of about 130°. There was ecchymosis localized to the outer side of the elbow, swelling, tenderness over the external condyle. Crepitus, false mobility and deformity were absent.

Diagnosis: Fracture of the external condyle of the left humerus, subsequently confirmed by a Roentgen ray picture.

Treatment: Acute flexion position as shown in Fig. 1, followed by proper after-treatment.

FIG. 1.—Case I.—Shows the acute flexion position and the manner in which the limb is retained in this position.

Subsequent History: Patient discharged with normal flexion, extension, supination and pronation.

CASE II.—Albert K., six and one-half years of age. A few days before coming to our clinic the patient tripped and fell on the outstretched palm of his left hand, with the elbow extended. He suffered from dis-

FIG. 2.—Case II.—An x-ray picture showing the lateral displacement of the fragments.

ability of the left elbow due to the severe pain which he experienced when he attempted to use same. Examination showed that the left elbow was held at an angle of about 160° extension, and was swollen and ecchymotic, the ecchymosis being about the elbow joint.

Tenderness, which was excruciating and localized to the lower part of the humerus, prevented a prolonged examination of the limb. Voluntary and passive flexion and extension were limited.

Diagnosis: Supracondyloid fracture of the left

FIG. 3.—Case II.—Showing the flexion and extension present when the patient was discharged.

humerus. A subsequent Roentgen ray picture (photograph 2) confirmed our diagnosis.

Treatment: Acute flexion, followed by the treatment previously described.

Subsequent History: Figs. 3 and 4 show the flexion and extension present at the time the patient was discharged.

CASE III.—Sidney E., eight years of age. Fell a distance of several feet striking on the outstretched palm of his left hand. Examination showed that there were marked swelling, disability, ecchymosis and deformity. Flexion, extension, pronation and supination were limited.

Diagnosis: A supracondyloid fracture of the left humerus, subsequently confirmed by a Roentgen ray picture. I might add that a wrist drop, probably due to an injury to the nerve, complicated this case. Fig. 4 is the x-ray picture. Note the posterior and upward displacement of the lower fragment, and the anterior and downward displacement of the upper fragment.

Epicondyles.—Either condyle may be fractured, the

FIG. 4.—Case III.—Roentgen ray picture showing the injury.

line of fracture starting above the condyle and running obliquely downwards into the elbow joint between the condyles. There is generally displacement forward of the broken fragment, which is very difficult to overcome. It is very important to set the fracture accurately.

In our series the internal condyle was the one most frequently fractured. The detached fragment is usually pulled downwards and forwards by the muscles attached to it. The displacement is slight as a rule and fracture is usually outside of the joint. After reduc-

FIG. 5.—Case IV.—X-ray picture showing the extent of injury.

tion place the limb in acute flexion as described above. Where reduction is impossible operation should be advised.

CASE IV.—Mildred K., seven years of age. A few days before coming to our clinic, she fell, injuring her right elbow. She complained of pain and inability to use the injured limb. Examination showed that the injured elbow was held in flexion of about 140°; there was ecchymosis over the inner side of the elbow; there was no deformity of crepitus, but there was excruciating tenderness over the internal condyle.

Diagnosis: Fracture of the internal condyle of the humerus with no displacement.

FIG. 6.—Case IV.—Showing normal flexion and extension at the time of discharge.

Treatment: Acute flexion position, with the proper after-treatment, early passive movements, massage and exercises.

Subsequent History: This patient was discharged as cured. Fig. 5 is the x-ray picture of this case. Note

the absence of displacement of the fragment. In spite of this there was marked disability and tenderness. Fig. 6, taken after the patient was discharged, shows normal flexion and normal extension.

CASE V.—Eugene H., four years of age. A few days

FIG. 7.—Case V.—Showing the flexion and extension present when the patient was discharged.

before coming to our clinic, he fell and injured his right elbow. He complained of pain and disability. Examination showed the right elbow held in flexion of about 100° ; there were ecchymosis localized to the inner side of the elbow, crepitus due to the fragment having been completely torn away, false mobility for the same reason, and excruciating tenderness over the inner condyle of the right humerus.

Diagnosis: Fracture of the internal condyle of the right humerus.

Treatment: Replacement of the fragment followed

FIG. 8.—Case VI.—A vertical picture showing the displacement of the fragment.

by the acute flexion position and later, early passive movements, massage and exercises.

Subsequent History: This patient was discharged as cured three weeks after the onset of the injury. Fig. 7, taken after he was discharged, shows the amount of

flexion and the normal extension present. Pronation and supination were normal.

CASE VI.—Michael S., four and one-half years of age. Fell and struck on his left elbow a few days before coming to our clinic. He complained of pain

FIG. 9.—Case VI.—From photographs taken one week after massage and passive movements had been begun, showing the flexion and extension present at this time.

and disability. Examination showed that the left elbow was held in flexion of about 130° , there were ecchymosis localized to the outer side of the elbow, crepitus and false mobility due to a complete tearing away of the fragment, and excruciating tenderness over the external condyle of the left humerus.

Diagnosis: Fracture of the external condyle of the left humerus.

Treatment: Replacement of the fragment followed by the acute flexion position and later passive movements, massage and exercises.

Subsequent History: This patient was discharged as cured. Fig. 11, photograph 8 is an x-ray picture of this case. Note the complete tearing away and displacement of the fragment. Fig. 12, taken some time

FIG. 10.—Case VII.—Lateral x-ray picture.

before the patient was discharged, shows the amount of flexion present. Fig. 13, taken at the same time, shows the amount of extension present. Subsequent to the taking of these pictures flexion and extension were normal.

CASE VII.—Steve M., five years of age. Fell and struck on his left elbow. Complained of pain and disability. Examination showed that the left elbow was held in flexion of about 120° . There were ecchymosis localized to the outer side of the left elbow, crepitus,

the injured limb. Examination showed that the right elbow was held in flexion of about 100° . There was marked swelling and ecchymosis about the elbow joint. Crepitus, false mobility were lacking. Tenderness localized to the outer side of the right elbow was very severe.

FIG. 11.—Case VII.—Anteroposterior x-ray picture. Note in Figs. 10 and 11 the displacement of the fragment.

false mobility and tenderness over the outer side of the elbow.

Diagnosis: Fracture of the external condyle of the left humerus.

Treatment: Acute flexion followed by early passive movements, massage and exercises.

Subsequent History: This patient was discharged as cured. Flexion, extension, pronation, and supination

FIG. 13.—Case VIII.—Anteroposterior x-ray picture. Note in Figs. 12 and 13 the separation of the fragment.

Diagnosis: Fracture of the external condyle of the right humerus.

Treatment: Acute flexion followed by passive movements, massage and exercises.

Subsequent History: This patient was discharged as cured. Flexion, extension, pronation, and supination were normal. Figs. 12 and 13 are x-ray pictures of this case.

Olecranon Process.—The fractures in these cases were near the base of the process. There was very little separation of the fragments. The cardinal signs of fracture were present and the diagnoses were confirmed by x-ray pictures.

Treatment: These patients were treated by

FIG. 12.—Case VIII.—Lateral x-ray picture.

FIG. 14.—Case IX.—From a photograph taken ten days after massage had been begun.

were normal. Figs. 10 and 11 are x-ray pictures of this case.

CASE VIII.—Alfred R., six years of age. Fell and hurt his right elbow one day before coming to our clinic. Complained of severe pain and total disability of

forms of mechanical apparatus. Operation was not resorted to and they recovered with a fairly normal degree of flexion, extension, pronation and supination. The method used, a very simple one, is one

in which a straight plaster of paris splint is placed along the arm and forearm, with a pad in the elbow bend so that the limb is not fully extended. The fragments of the olecranon process were kept in position by means of narrow strips of adhesive plas-

FIG. 15.—Case IX.—From photographs taken at the end of treatment, showing the degree of flexion and extension present.

ter applied with their center above the fragment (over which is placed a small pad of lint) and the ends are brought obliquely downward to the sides of the splint below the elbow. The strapping required daily inspection and frequent renewal. The marked effusion which was present necessitated the use of an ice bag.

Subsequent Treatment: The limb was kept in the extended position for three weeks. From time to time the splint was removed and passive movements given. Care must be taken to avoid separation of the fragments. In spite of this early passive

FIG. 16.—Case IX.—AL X-RAY PICTURE SHOWING THE EXTENT OF THE INJURY.

motion and massage there was considerable stiffness, which was eventually overcome by persistent careful massage, baking, passive movements, and exercises.

CASE IX.—Philip G., fourteen years of age. Fell and

struck on his right elbow. Complained of pain and inability to use the injured limb. Examination showed that the right elbow held in flexion of about 140°. There were ecchymosis localized to the posterior part of the elbow, excruciating tenderness over the base of the olecranon process, slight crepitus and false mobility.

Diagnosis: Fracture of the olecranon process of the right ulna.

Treatment: As previously described.

Subsequent History: At the present date the patient has normal flexion, supination and pronation, extension of about 175°. Fig. 14 taken ten days after passive movements, massage and exercises had been instituted, shows flexion of about 90° and extension of about 135°. Pronation and supination were normal. Fig. 15 taken some time later, shows extension of about 160°, and flexion almost normal. The ultimate result in this case will be normal extension. Fig. 16 is an x-ray picture of this case.

The following is a summary of our cases giving the end results obtained:

Internal condyle, 24; R. 13; L. 11. Sex: Males, 16; females, 8. Age: 10 years or below, 17; above 10 years 7. Discharged normal, 24.

External condyles, 14; R., 8; L., 6. Sex: Males, 13; female, 1. Age: 10 years or below, 9; 10 to 15 years, 5. Discharged normal, 14.

Supracondyloid fractures, 8. Sex: Males, 8. Age: 10 years or below, 6; 10 to 15 years, 2. Discharged normal, 7; discontinued treatment, 1 with Flex. 70°; Ext. 160°.

Olecranon Process, 4; R., 3; L., 1. Sex: Males, 3; female, 1. Age: 10 years or below, 2; above 10 years, 2. Discharged normal, 2; discontinued treatment, 1 with Flex. 90°; Ext. 140°. Still under treatment, 1 with Flex. normal; Ext. 160°.

Conclusions.—1. Every case of injury to the elbow where the diagnosis is doubtful should be placed in the acute flexion position until the diagnosis is cleared up by the Roentgen ray (except fractures of the olecranon process).

2. Begin massage and passive movements about the tenth day and continue thereafter until the movements in the elbow joint are normal and free from pain.

3. Guard against the displacement of the fragments when passive movements are begun as faulty reduction causes periosteal proliferation that locks the joint.

4. Proper retention is just as important as proper reduction.

5. These few precautions will prevent a great deal of unnecessary suffering and disability which usually follow too long immobilization, improper reduction and improper retention of the elbow joint.

6. I wish to express my gratitude to Dr. Samuel Kleinberg for his kind encouragement and to Dr. Jacob Bower for the x-ray pictures.

1051 BOSTON ROAD

TRICHINIASIS.*

BY MICHAEL G. WOHL, M.D.,
OMAHA, NEB.

PATHOLOGIST TO THE NICHOLAS SENN HOSPITAL, FORMERLY
PROFESSOR OF PATHOLOGY OF TEMPLE UNIVERSITY AND
PATHOLOGIST OF HOWARD AND SAMARITAN
HOSPITALS, PHILADELPHIA.

SINCE Zenker¹ in 1860 made the accidental post mortem discovery of the trichinæ in a girl who died of typhoid fever, a great number of cases of human trichiniasis have been reported. It has been estimated that up to 1914 there were reported in the literature over 15,000 cases among which 830 proved fatal. In some epidemics the mortality reached 16

*From the Pathological Department, Nicholas Senn Hospital.

per cent. or even 30 per cent., as in the Hedersleben epidemic in 1865.² Cases of sporadic trichiniasis are more common than hitherto supposed, yet trichiniasis is very frequently overlooked, and mild cases are almost never diagnosed. This is probably due to the fact that the disease so often resembles typhoid fever, or "muscular rheumatism." Therefore, we believe that it would not be amiss in the report of our cases to review briefly the disease in general.

Man acquires the disease from eating raw or rare pork. The larvæ will stand considerable heat. Melvin,³ chief of Bureau of Animal Industry of United States Department of Agriculture, recommends that pork should be cooked until it is no longer red but white in all portions, at the center as well as near the surface. The larvæ may remain alive in the muscle for years; according to Sicard⁴ they may live in the muscle of the hog as long as twenty years. In man they have been known to retain their vitality within the muscle as long as twelve years.⁵

Upon being swallowed, the cysts in the raw or in-

FIG. 1.—Showing the hyaline degeneration and marked round-cell infiltration.

sufficiently cooked pork are destroyed in the stomach, and the larvæ pass to the small intestine and remain in the bowel for three days until they reach full development; then they copulate, and the male worm soon dies after copulation. The female remains within the bowel for from five to twelve weeks, and burrows beneath the submucosa of the duodenum and deposits the embryos in the lymphatic spaces. Many of the embryos escape with the feces, although they are rarely to be demonstrated. From the lymph channels of the intestines the embryos are carried to the thoracic duct, from here to the superior vena cava and the heart; however, they very rarely lodge within the myocardium itself.

Askanazy⁶ found the embryos in clots in the heart and hemorrhagic foci of the lungs of rabbits upon which he experimented. The embryos then enter the striated muscle, especially the diaphragm, tongue, muscles of the neck, larynx, etc., and become encysted. At first they involve the sarcolemma but soon go to the muscle fiber itself and produce degenerative as well as inflammatory changes, there

being a round cell infiltration in the intermuscular tissue, an accumulation of the eosinophiles, and formation of fibroblasts, also hyaline degeneration. After a time all the cells become absorbed and the rest is changed into connective tissue, or a clear chitinous cyst results in which the parasite lies coiled up, surrounded by granular detritus. In making a diagnosis one may not find the embryo encysted in the muscle, yet the degenerative changes are present in the great majority of cases. The excised piece of muscle from one of our cases shows a marked round cell infiltration and a hyaline degeneration. The section from another case posted at the Garretson Hospital, Philadelphia, shows the trichinæ coiled up in the cyst.

The secondary pathological changes of the different organs of the body which are produced by the toxin of the trichinæ are of a degenerative nature. That the trichinæ secrete a toxin has been disputed by a number of men, but the work of Romanowitch⁷ seems to have settled this question. He transferred the toxin contained in the serum of the infected animals to rabbits by subcutaneous injection.

Gastel,⁸ however, believes that the toxin of trichinæ is not a true toxin in the sense of Romanowitch; yet the violent temperature fluctuations, the edema, the extreme fatigue, and the capillary hemorrhages cannot be explained merely by mechanical disturbances set up by the parasite.

Flury⁹ has shown that the poisonous products are derived from trichinæ, and besides these toxic products there is also absorption of chemical products which arise from degenerated muscle tissue. That there is a definite change in the muscle metabolism can be seen from the high creatinin excretions in one of our cases (Creatinin No. 40). This is in accord with the work of Flury and Groll,¹⁰ who demonstrated an alteration in the muscle chemistry in trichiniasis.

Herrick¹¹ believes that the constant inoculation of the patient with the foreign protein from the invasion of the body by the embryos and split products of the degenerated muscle, accounts for the symptom complex of trichiniasis. The marked eosinophilia which is so characteristic of the disease, is undoubtedly due to the stimulation of bone marrow by the same products, since¹² Ahl, Schittenhelm, Schlecht, Herrick, and others have established the fact that introduction of foreign protein or its split products by parenteral routes into animals is followed by a marked eosinophilia. The lesions are produced by the poisons—exogenous secreted by the trichinæ and endogenous formed by destruction of muscle tissue—and consist, as we pointed out, of parenchymatous degeneration of the kidneys, liver, and myocardium, and a low-grade inflammation of the brain.

Honne and Höffner¹³ observed delirium and dullness in cases of trichiniasis. In our case the toxin of trichinæ precipitated an epileptic fit, while the patient had two epileptic attacks within six months in one of our cases (creatinin 40). This ing the disease, which was of about five weeks' duration, he had one attack.

That the muscular symptoms are due to both the toxemia and the mechanical irritation caused by the parasite is too well known; that the nervous symptoms are due to this combination seems likewise probable. Van Cott and Lintz¹⁴ for the first time demonstrated the presence of trichinæ in the spinal fluid.

Blood.—We owe to Brown and Thayer¹⁵ the demonstration of the increase of eosinophiles in trichiniasis. From normal 1-4 per cent. they may rise to 68 per cent. Kerr¹⁶ has reported an eosinophilia of 86.6 per cent. In our case the eosinophiles were

FIG. 2 Showing the cysts containing the coiled-up trichinae.

as high as 46 per cent. The increase in eosinophilia dates, according to Opie,¹⁷ from the beginning of migration of the embryos, the maximum eosinophile count being at the time of migration of the parasite from the intestine to the muscular system. Trichinae not only produce a toxin, but also act as a true antigen, giving rise to the formation of antibodies.

Ströbel¹⁸ made use of this fact for diagnostic purposes, employing the complement fixation test. He found that the antibodies persist as late as a year and a half after the infection, although they do not appear in the blood before the tenth week. Herrick and Janeway¹⁹ found the trichinae in the blood. Lamb²⁰ also demonstrated their presence in the blood as early as the sixth or seventh day after the infection.

Symptoms. Symptoms of the disease appear

about two weeks after ingestion of infected pork, some times earlier. The symptoms of gastrointestinal irritation are diarrhea, abdominal cramps, and tenderness in the epigastrium, the symptoms bearing close resemblance to typhoid fever. On migration of the parasite there are severe muscular pains and high fever; this fact may cause the disease to be confused with muscular rheumatism. The symptoms which are due to absorption of toxins are anorexia, malaise, headache, continued fever, great prostration, mental dullness, delirium, and quite commonly edema of the face and ankles. Minot and Rackman²¹ point out that the pulmonary symptoms, such as cough and râles at the base of the lung, are severe enough to lead to serious consideration of an actual diagnosis of a purely pulmonary condition. Symptoms such as pain and burning in the eyes may be present. Edema is a common sequel of the disease.

Diagnosis.—The diagnosis is made from the blood examination showing high eosinophile count, and by finding the trichinae or hyaline degeneration with round cell infiltration in an excised piece of muscle. In the stools the trichinae are rarely found, for according to Fielder²² trichinae are dissolved in the small intestines; however, the presence of Charcot-Leyden crystals is of some value. Persistent search for parasites in the stools made by Mrs. Mary Griffith of our laboratory failed to show them.

Treatment.—Administration of anthelmintics is of questionable benefit to the patient. As the parasites burrow beneath the epithelium of the crypts and villi and discharge their young into the tissue itself, it is doubtful if cathartics and intestinal antiseptics do any good. Osler²³ recommends the use of thymol and calomel.

After the parasites have left the intestines, all treatment must be symptomatic and supportive. Since specific antibodies have been demonstrated in the blood of patients suffering from trichiniasis we would think that the administration of vaccines prepared from trichinae of infected hogs would be a logical step. Merrick²⁴ has given a method of isolating trichina embryos free from muscle fiber by digesting the muscle in hydrochloric acid and pepsin, and precipitating the parasite by centrifuging. In conclusion we shall outline briefly the

FIG. 3 Showing the increase in eosinophiles.

history and course of the disease in a case treated at the Nicholas Senn Hospital.

R. M.; age 32 years; entered the Nicholas Senn Hospital November 7, 1914. Past history, no typhoid or pneumonia. Ordinary diseases of childhood. Some spells of dizziness during the past four years and in the last six months has twice lost consciousness and has fallen. No history of tuberculosis or chronic cough.

The present illness began about three weeks ago. He had symptoms similar to the prodromes of typhoid for about a week, then he began to have an afternoon rise in temperature. He did not go to bed. For one week before his admission to the hospital his temperature reached 100° each afternoon. Ten days before entering the hospital he had a Widal made, which was negative and a blood examination which is shown on the accompanying chart. He was advised to come to the laboratory every two days for a blood examination. On November 7 his eosinophiles had reached 18 per cent. Trichiniasis was suspected.

He entered the hospital and a piece of muscle was excised and the characteristic microscopical findings above described were noted. During the three weeks that he was an ambulatory patient he suffered much from muscular pains and soreness, fatigue, and exhaustion. The pains while present involved the deltoid and flexors of the forearm and nearly all the muscles of the leg. No pectoral pain at any time, no chills, some slight diarrhea in the beginning. The patient had lost much in weight and cerebrated with much difficulty, in fact his mental lethargy was quite marked for some days after his admission to the hospital. On the fifth day after entering the hospital, he had a severe epileptic convulsion.

Temperature at time of entrance was 100° and respiration 18. The temperature rose to 101° and came down to normal and then varied from 102° to normal. Respirations varied from 18 to 24, and pulse from 92 to 102. He remained in the hospital for two weeks, at the end of which time the muscular pain and soreness had practically disappeared, temperature was normal, appetite much improved, and he had gained some in weight. The treatment instituted was eliminative, intestinal antiseptics were given, salol being the principal one. A simple supportive treatment was about all that could be done. The course of the disease lasted between five and six weeks, as nearly as we can figure from the history. A laboratory report is appended, which shows the blood and urinary findings.

Laboratory Report.—The absolute leucocyte count varied between 5400 on admission and 15,400 at height of disease. The eosinophile count is indicated on the chart accompanying. Widal negative. Diazo negative. Urine analysis: creatinin 40, the other urinary findings of no importance.

The history of the other case is not known, as the body was sent by the Anatomical Board, Philadelphia.

I wish to express my thanks to Mrs. Mary Griffith for the laboratory reports.

FLAT FOOT: ITS RELATION TO NEURITIS AND ITS TREATMENT.*

BY WILLIAM MARTIN, M.D.,
ATLANTIC CITY, N. J.

DURING recent years there has been a clearer conception of the part played by postural defects upon the nerve structures. An example is that of scoliosis in its effect upon the various nerves supplying the parts. There seems, however, to have been little or no attention given to the part played by relaxed or fallen arches upon the sciatic nerves, so far as I am aware, in the present day literature, which will account for this paper, as during the past few years my attention has been attracted to this condition by a series of most interesting cases.

As a rule, these patients apply for relief from what they think to be flat foot, as the pain is in the main referred to the arches and ball of the feet. They may mention as an incident that there is an occasional backache, but the main complaint is that of the feet. As will be shown later, there is almost invariably a painful response to the static wave current. Whether the nerve inflammation is primary or secondary to the relaxed or fallen arches is a problem to be solved in each individual case. In some cases I am satisfied that the nerve involvement has been primary, and through nerve innervation, allowing a subsequent relaxation of the arch or arches. In other cases the involvement has been secondary, through a form of traumatism due to postural defects producing pressure and tension.

In order to bring clearly to mind some of the reasons for arch drop, it will be well to refresh our memories with a short statement of the anatomical features of the arch. As you know, the foot in its construction is composed of two arches: the antero-posterior and the lateral. The former is formed by the os calcis, scaphoid, three cuneiform, and the metatarsals with the astragalus as a keystone. These are held together firmly by ligaments, the plantar binding the os calcis to the scaphoid. This powerful ligament, together with the long plantar, binds firmly together the various bones of the foot and completes what has been termed the first line of defense of the anteroposterior arch. The second line of support consists of the short muscles of the foot together with the tibialis anticus, which helps by lifting the proximal end of the first metatarsal bone. The lateral arch is an imperfect one, as its support is at the outer side only, the body weight being borne by the os calcis, cuboid, and

*Read before the New England Association of Physical Therapeutics, at Boston, November 23, 1915.

5th metatarsal. The arch rises upward and inward, and its free unsupported edge is formed by the astragalus, the scaphoid, and the internal cuneiform, with the first metatarsal.

The main support of the lateral arch is from the tendon of the peroneus longus, which crosses the foot diagonally from the cuboid to the first cuneiform, and by the ligaments which bind together the adjacent bones; it also receives some support from the tibialis anticus.

The line of body weight supported by the arches is directly down through the tibia and astragalus, which weight tends to spread the arch and stretch the long and short plantar ligaments. This brings the inner side of the foot down and the lateral arch yields to the flattening process, as it is the unsupported part of the arch that gives way. The flattened instep projects inward, causing a bulge at the centre of the inner line of the foot, the outline changing to a convex instead of a concave, or even a straight line.

The typical flat foot shows a turning out of the line of the heel, with a convexity of the inner side of the foot, and a concavity of the outer side, while a tracing of the foot shows no instep.

A great deal of study and investigation has been given to the subject of flat foot by orthopedic and

other surgeons, and various mechanical appliances and shoes have been placed before the suffering public with the view of correcting this condition.

The greatest sufferers from this form of painful feet are those whose occupations require much standing, and the obese. Faulty posture is another factor which will throw the body weight from the normal line and bring uneven pressure to bear upon the arches. This has been ably demonstrated by Dr. Percy W. Roberts of New York City in the *N. Y. Medical Journal*, Aug. 28, 1915, and I will therefore use some of his statements in explanation of the mechanics of flat foot.

He stated that "it seems to have escaped observation generally that the os calcis has a more or less globular shape of its inferior bearing surface, and that because of its firm union to the anterior part of the foot and its rounded bearing surface, is one of the most important single factors in the production of lateral instability of the foot." As he has so well demonstrated, the weight of the body out of the center line will tilt this bone one way or the other, according to the line of weight. It is purely a question of mechanics; therefore if the os calcis is rotated, the rest of the foot must rotate with it. The method of correction of this rotation will be considered under the head of treatment.

The association of sciatic inflammations and irritations with flat foot is more common than is generally supposed. This can be demonstrated by the use of the static wave current applied to all cases

that come under the care of the physician for painful feet.

The amount of pain is not always commensurate with the amount of foot drop, as some cases of relaxed arches will cause more pain than the flat foot. If in time this relaxation develops into a full and complete flat foot, the nerves sometimes adapt themselves to the changed conditions, and thus the suffering abates. Unfortunately this is not a constant result, for in my experience, some have shown increasing pain with the developing flat foot.

A careful examination of each case presenting must be made in order to get the best results of treatment, and by this I mean, an examination of the feet bared, and from all sides, together with tracings, if need be. With this I deem it essential that the wave current be applied to the course of the sciatic nerves and their branches, following its full course down the legs, if necessary to find the most sensitive parts. Usually the sciatic notches will be found the most painful, and the tenderness lessening as the nerve is followed downward.

The treatment of this condition is more or less complex, and cannot be done empirically. Mechanical measures have been long advised and used, with varying results. The arch-lifts, lately of the adjustable kind, have been mainly relied upon, and the adjustment left largely to the patient, who cannot have a clear conception of the needs. This often entails much suffering from the bruising of the tender structures pressed upon, and in some cases under my notice, has been more painful than the actual foot drop itself.

A careful examination will show whether the condition is one of relaxation of the arches or a full flattening, and the treatment can then be logically applied, as it must necessarily differ in the two types of cases. If the former, exercises alone with

the treatment of the sciatic nerves with the static wave current applied as previously suggested, for a considerable length of time, will usually bring about the desired result. If the full flat foot is

found, remember this rotation of the os calcis, as it may prove to be the one factor by which a correction will mean a cure, if used in conjunction with the other measures necessary. Dr. Roberts has solved this problem very satisfactorily in my estimation, as the one case cited below will demonstrate. These plates are totally different from any on the market, and must be made for each individual case, as a perfect fit is absolutely essential. A plaster cast of the feet must be made, full length to the end of the great toes, allowing the plaster to come well up the sides and back of the heels, and to the full height of the side of the great toes. From these casts the manufacturer makes his perfectly fitting heel plates, which correct the rotation of the os calcis, and securely hold it in its proper position. These plates are made from light but strong metal, and fit the shoe so well that the wearer forgets their presence, differing so decidedly from the ever present arch lifts, which cannot be forgotten.

The treatment by exercises is one of the very important factors toward a cure. In light cases of relaxed arches, they need not be practised longer than a few months, but in the severe types, they should be pursued for at least a year or more, according to the exigencies of the case. At the beginning I recommend only three of the exercises following, as the muscles tire and become sore from them, but gradually the rest can be added one by one, as the patient becomes accustomed to them, as he usually does soon.

These exercises are a modification of these recommended by Dr. McKenzie in his work on "Exercise in Education and Medicine," 2d edition:

1. Patient sitting, leg extended and supported just above the ankle. Grasp the right foot just above the ankle with the left hand. Place right hand on sole of foot. With thumb pointing toward toes, grasp foot firmly, circumduct foot slowly as follows; extension, inversion, flexion, eversion. This should be done by attendant with as much force as can be used without pain, and repeated thirty times. Each part of the movement should be separated by a pause.

2. These same movements done by patient without help.

3. Patient standing, toes in and heels out, and about 12 inches apart. Rise on toes and press out slowly. Repeat thirty times.

4. Standing, feet parallel and 6 inches apart. Raise the inner side of the feet, throwing the weight on the outer side. Repeat thirty times.

5. Standing with feet parallel, weight resting on outer side of the feet. Walk forward and backward thirty steps, keeping feet parallel, and forcing down ball of feet.

6. Standing, feet 12 inches apart, and parallel, knees bending, and outward pressing.

7. Standing, feet 6 inches apart and turned in. Rise on toes and walk forward and backward thirty steps, crossing feet and keeping toes in.

8. Standing firm, right lunge forward, neck firm, bend right knee until heel is forced from floor, keeping weight on the outer side of foot. Repeat ten times, and do the same with the left.

9. Standing, feet parallel, 6 inches apart. Sway slowly forward and backward on heels and ball of feet, chest active and chin in.

10. Raise heel one inch from floor and walk without bringing heel down, as if the heel was painful. May be done repeatedly with both heels.

In all of the cases associated with a neuritis, there must be the same dietetic care used as in the ordinary types of nerve inflammation, with a toxicemic intestinal condition underlying. In addition to the static wave current, static sparks, the brush discharge, and resonator effluve, may all be used, according to the best judgment of the operator. This line of treatment will be best illustrated by a brief citation of three typical cases.

CASE I.—This case is that of the writer, who can testify personally to the suffering of relaxed arches. Some years previous to this condition I had received a severe strain of the sacroiliac joint from a difficult forceps labor case, which had given me considerable pain, and had developed into an arthritis, which diagnosis was substantiated by roentgenograms. A few years ago, when changing from general practice to my present work, I began to suffer with my back, the pain extending to the feet. My conclusion was that the old injury was responsible for the pain in the back, and constant standing accounted for that in the feet. Gradually the feet became progressively worse, and naturally the thought was that the arches had fallen, so I applied to my instrument maker for arch lifts to correct this supposed condition. An examination made by him, corroborated this supposition, and they were accordingly placed. The relief was transient, following the sore bruised stage which promptly appeared. Some time later I removed them, and sought relief by wearing a much lauded type of shoe that was guaranteed to cure all kinds of flat foot. These shoes were worn with little more relief, and were objectionable on account of their shape and weight. Still suffering and without much hope of relief, during an especially severe attack of the arthritis, I applied the static wave current to the part, with a plate large enough to reach over the sciatic notch. To my great surprise, as the pain subsided in my back, it did also in my foot. This gave me a thought, and I followed out this line of treatment for a considerable time, with a final end of my foot trouble. It was this experience that led me to examine other cases carefully and use the static wave current in my examinations of all cases of foot drop and relaxations, and this care has led me into a most interesting line of experiences and results.

CASE II.—This case is one of a physician druggist, who had consulted a number of physicians for relief from painful feet, which had been diagnosed by all in turn as flat foot, but all were unable to give him the desired relief. An examination of his bared feet showed relaxed but not dropped arches. Examining his sciatics in the usual way by means of the static wave current, the expected result was immediately found. The sciatics were so painful that he could bear but a half-inch spark gap current. He stated at once that he did not remember ever having pains referred to his back or legs, except at rare intervals there had been some leg spasms of a mild type.

Treatments were pursued daily for about six weeks, with occasional interruptions. Improvement was prompt, and a positive cure was secured at the end of this time. In this case there were no exercises used, and nothing but sparks in addition to the static wave current, which is evidence to my mind, that the relaxed arches were the result of sciatic neuritis.

CASE III.—A young lady, school teacher, has been suffering for three years with severely painful feet, and pursuing her vocation under great difficulties, as can be imagined. As her history is by far the most interesting one of all, I will give it in more detail.

A little over three years ago, the arch of her left foot gave way suddenly in school, and she was thrown to the floor helpless and suffering great pain in the foot. She was helped up and to her home, and placed in bed. Both feet became swollen and inflamed, the left more particularly so, and for five weeks she was confined to her bed. The physician in charge called the trouble rheumatism, and placed her upon remedies for this condition.

Following the acute stage, there has been ever since a great deal of pain in the feet, more in the left, and this pain and soreness has extended to the hips. During the three years that have elapsed, she has consulted several physicians, but without relief to any great extent. During the three years she has worn arch lifts of the adjustable type, and has gradually increased the

elevation, keeping up a constant soreness in addition to the pain ever present, although there has been some improvement in that regard.

During the mid-summer just past, she came under my care, following a short course of static wave treatments applied over the leg muscles to relieve muscular spasms, given by a physician in a neighboring city, but which did not bring the relief desired.

A careful examination of the bared feet showed a full and complete drop of both arches. Manipulation of the feet showed an absolute relaxation of the muscles and ligaments of the lateral and anteroposterior arches of both feet. Examination of the sciatics of both sides showed acutely painful responses, and the soreness could be traced all the way down to the feet, more severe in the left nerve. The posterior view of the feet showed decided rotation of the os calcis, more exaggerated on the left, which has been all through the more involved. Her general health was good, no great amount of intestinal toxemia found, kidneys were normal, but smears from the tonsils showed some bacilli, streptococcus and staphylococcus, and the tonsils while small, were diseased. No doubt this infection has played a part in the sciatic involvement. On this account, there has been some surgical attention given to these. The diet was made a restricted proteid type, and occasional doses of castor oil administered, so that the intestinal condition soon cleared. The exercises mentioned in this paper were instituted in the manner stated, and after a time the sore muscle condition abated, and the whole ten were used faithfully, and are still in use.

From the start, the high candle-power lamp was used to the extent of a decided hyperemia, over the whole back and hips. This was followed by long sances of the static wave current applied to the sciatic notches and over the nerve course, and some of its branches on both sides, as the painful places were found. For a time, owing to the time consumed in the treatments, I used the static induced current, thus cutting the time in half, and with equally as good results, so far as I could determine. Static sparks were used liberally at each treatment, and were applied all along the course of the nerve in each leg.

Noting the rotation of the os calcis, the case offered a most excellent chance to test the method of Roberts, and as she was willing to go through the troublesome ordeal, I made plaster casts of both feet, and sent them on to the manufacturer in New York for the purpose of having the heel plates made. These were perfectly satisfactory in the fit, and have been worn with absolute comfort. She unhesitatingly states that at the end of two months of treatment, during which time these plates were worn, she has secured perfect relief from all pain in the feet, and all that remained was some soreness and ache in the mid-thigh region, particularly after a long auto ride, but that she can walk for miles without realizing that she ever had painful feet. This patient is still under treatment, remaining longer in order to make a complete recovery from all the pain in the sciatics, which will not amount to a great deal more time.

This case illustrates the most severe type of flat foot, while the other two represent the milder forms, and the three are selected for the purpose of typifying the relationship of nerve pains, either associated or caused by relaxed or fallen arches, and I trust will be in some measure helpful to others in giving relief to this class of sufferers, of whom there are so many.

MARYLAND AND PACIFIC AVENUES.

CIRSOID ANEURYSM TREATED BY THE DIRECT APPLICATION OF BOILING WATER.

BY JOHN A. WYETH, M.D.,

NEW YORK

SENIOR SURGEON, NEW YORK POLYCLINIC MEDICAL SCHOOL, AND HOSPITAL.

THE following is the record of a case of extensive arterial angioma (cirsoid aneurysm) of the right temporal and parietal regions in which coagulation

of the blood and vascular occlusion were effected by the direct application of water at a high temperature.

Charles J. Meilke, 26; connected with the United States Army Medical Service, Second Division, Field Hospital Company No. 3, El Paso, Texas, consulted me at the Polyclinic Hospital, Dec. 1, 1914, with the following history:

In 1906 he was thrown from an automobile, striking with considerable violence upon the right temporal and parietal region. Although the scalp was scraped and severely bruised, there were no symptoms of fracture of the skull, and the patient recovered promptly from the immediate effects of the accident.

In 1908, he first noticed an abnormal throbbing sensation in the temporal artery, near the zygoma. This gradually increased, until the forehead and a large portion of the right parietal region was a mass of tortuous arteries, in which a distinct aneurysmal bruit and fremitus were present. The patient informed me that Dr. Bannister, U. S. A., referred him to the Mayo clinic, and that an operation was not deemed advisable.

On Dec. 7, 1914, at the Polyclinic, the field of operation was made analgesic by free infiltration with one-half per cent. novocain, and about one-fourth of the vascular area was coagulated by boiling water and steam subdermally administered. In order to maintain the necessary degree of heat (although boiling water was placed in the steel syringe) after the needle was introduced, a candle was held under the barrel, until the noise of escaping steam could be distinctly heard beneath the scalp. The patient complained of no sense of pain. This procedure was repeated on three other occasions, with an interval of two days, until the mass was solid and pulsation absent.

He was discharged, cured.

So far, since I introduced this method of treating angiomata in 1902, it has been uniformly satisfactory in a very considerable number of cases of arterial and venous angiomata.

211 LEXINGTON AVENUE.

TREATMENT OF DEMENTIA PRECOX WITH SODIUM NUCLEINATE.

BY CHARLES F. READ, M.D.,

PEORIA, ILL.

ASSISTANT SUPERINTENDENT PEORIA STATE HOSPITAL.

INASMUCH as there has been some discussion of late concerning the use of sodium nucleinate in dementia precox, it seems wise that cases treated in this manner should be reported until a sufficient number are assembled to clearly testify either for or against this method. The treatment is an empirical one based upon the observation that mental cases of this type occasionally improve during the course of infection, and that injections of sodium nucleinate tend to produce fever and leucocytosis.

The writer has not used the Lundvall formula, but has given sodium nucleinate according to the method of Donarth, who uses it as a 10 per cent. solution in physiological salt solution with the addition of small amounts of sodium cinnamate, of which solution from 5 to 40 c.c. is given in rapidly increasing doses, the average dose being about 25 c.c. The injection is made under the skin of the abdomen with a large glass syringe fitted to a lumbar puncture needle which is especially sharpened so as to give it a long, sharp bevel. When given in this way, the treatment, though painful, is not severe and the solution is absorbed rapidly. Ordinary aseptic precautions are observed and the solution is usually made up fresh for each administration, though it can be kept for some time in a refrigerator without deterioration. There has been no abscess formation and practically no induration following some 150 injections. Aside from the in-

jections, the patients received only routine care. The cases were unselected save that, so far as possible, newly admitted patients were treated. The previous duration of mental trouble ranged all the way from six months to several years.

It would be tiresome and unnecessary to describe at length all of the cases treated. The following are typical of the results obtained. All were patients in the Chicago State Hospital.

CASE I.—Catharine R., aged 23. A young woman with a history of onset a year previous to admission, when received was very indifferent to her surroundings, seemed somewhat suspicious at times, refused to eat, and answered but few questions. Treatment was begun soon after admission and eight injections in all were given, rapidly ascending to 25 c.c. at intervals of about a week. There was no rise of temperature save once to 100.4° and the leucocyte count made upon five occasions ranged from 6,600 to 12,400. After eight treatments, the patient became quite normal in conduct and talked freely, but had no insight. She was paroled in excellent condition and has not been heard from since.

CASE II.—Selma A., aged 32. Onset six months before admission, but possibly much longer, was said to have always been somewhat peculiar and seclusive. She seemed depressed when admitted and had ideas of reference, voices seemed to come to her from the ceiling, she had a feeling that she could not think, worried over sexual indiscretions, and thought she had some evil disease. She was given eleven treatments beginning with 3 c.c. of the solution and ascending to 25 c.c. After the first treatment her temperature rose to 103° but subsided in a few days and after this did not go higher than 100.6°, upon which occasion the leucocyte count rose from 9,800 to 15,400. During treatment, patient improved, became less seclusive, seemed more cheerful, and worked at fancy work. She was paroled after some months very markedly improved, but still odd in her behavior and without insight. There is some question here of a manic-depressive psychosis but the weight of the evidence favors dementia precox.

CASE III.—Stella N., aged 28. Onset six months previous to admission. She was resistive, restless, and refused to eat when first admitted. She laughed a great deal, had very disturbed spells in which she screamed and threw herself about the room and impulsively attacked the physician. Treatment was commenced some months after admission. Ten injections were given without any noticeable rise of temperature, and without alteration of the white blood count. The patient made no improvement whatever.

CASE IV.—Sarah S., aged 18. This case is a recurrent one, presenting stupor without retardation. Unfortunately complete notes are not at hand. The patient received twelve treatments from the latter part of April to the latter part of July without apparent effect. The leucocyte count varied from 5,500 to 9,600 and the temperature never went above 100.4°. She did not improve until several months after cessation of treatment when she cleared up rapidly and went out apparently well but without much insight. The same improvement had been noticed on a previous occasion without treatment.

CASE V.—Jennie M., aged 22. Onset was about three months previous to admission. She had been in another hospital where she was restless, careless, indifferent, noisy, irritable, hallucinating, and delusional. She was removed without change and returned to the Chicago State Hospital where her condition, when admitted, was essentially as described. Sodium nucleinate treatment was instituted and she began to improve gradually. Ten injections were given, with but slight temperature rise on two occasions, and no leucocyte increase. Three months after treatment was begun, she was paroled in excellent mental condition, but with no insight.

CASE VI.—Edward McC., aged 22. This patient when admitted was an acute case of short standing, was very untidy in habits, had the habit of urinating upon other patients, and was much disturbed at times. Three treatments were given. Following the first the temperature went to 101.6° and the leucocyte count from 9,400 to 16,800. Following the second treatment without rise of fever, leucocyte count went to 20,800. We have no record of the third treatment. Following the first treatment the patient improved in his conduct

remarkably but relapsed somewhat and again improved following his second treatment. This improvement was noted to be rather like that of a bad boy who feels he is being punished and must mend his way. However, the patient continued to do much better and finally escaped, since when he has not been heard from.

CASE VII.—George D., aged 27. This patient has been in the hospital for three years and is a typical case of hebephrenia. Ten treatments were given without material result, although with a change to another ward and some very simple work in the industrial shop he improved enough to cause his parents great satisfaction.

CASE VIII.—Bessie S., aged 19, colored girl. Onset two weeks previous to admission when she became worried, refused to eat, had screaming spells, feared the devil, struck her mother, etc. Upon admission she was restless, assaulted the night nurse, assumed constrained positions, repeated words and phrases over and over, was spoon-fed, and remained in bed in a stuporous condition much of the time. She received eight treatments. Following the first treatment her temperature went to 100° and with each injection there was a rise of two to four degrees. The leucocytes varied from 11,000 to 14,000. The treatment extended over two months, following which she began to improve quite rapidly and was finally paroled in what was apparently a normal condition, though she had very little insight.

CASE IX.—Oswald W., a boy of 16. A history was difficult to obtain because the father is not bright and does not talk English, but it would seem that the boy had never been considered a defective and had had an amount of schooling commensurate with his age. Some time before admission he had an elated period, but a month previous to admission became depressed, refused to eat, and stood about staring and pointing to the wall, etc. When admitted he was agitated, thought he was going to die, was restless, untidy, moaned and cried, practised self-abuse continuously, was fed by persuasion, and assumed constrained attitudes. Just previous to treatment he was upon a ward for the untidy, in an apparently stationary condition but after one treatment of 10 c.c. he reacted with a high fever and over night became, as his nurse expressed it, "50 per cent. better." He received three more treatments and his improvement continued until he became apparently himself again and was removed by his father. At this time he had very little insight. He could not explain his previous difficulties save that he had had a pain in the head. He knew he had talked much and worried about the police being after him. He professed not to remember his practise of self-abuse. He recalled that he had been untidy but could not explain this, other than that he thought he was to be drowned when taken to the bathroom. He refused food because he had no appetite and could not at all explain resting stiffly on his elbow for hours at a time, talking through clenched teeth, etc. After leaving the hospital he obtained employment but soon complained that he was overworked. He was returned to the hospital in the course of a few weeks and at that time was in a curious state, closely resembling that seen in some high grade defectives during a state of mild excitement. He was quite irresponsible, teased other patients, constantly complained, and asked to go home. He was finally paroled again, and again returned a short time ago in a condition closely resembling catatonic excitement. The diagnosis here of course, is in question, lying as it does between that of a period of manic-like excitement in a defective, and catatonic precox. The case is interesting in view of the sudden great improvement following immediately upon the injection of sodium nucleinate in a patient who was apparently in a stationary condition.

CASE X.—Joseph D. A case of acute onset in a young alien. When admitted he was quiet, stupid and mute, later on was noisy, at times would attitudinize, smile peculiarly and refuse food, would allow food to remain in his mouth, would sit and look out of the window by the hour or stand in a corner. The patient received seven treatments with a temperature rise upon three occasions to 102°. White blood cells ranged from 6,800 to 14,000. At about the time the last treatment was given, the patient showed a change, became interested in his surroundings, smiled, talked, and complained of being among untidy patients. When placed upon another ward he improved rapidly, becoming very pleasant and a good worker.

The above cases are sufficient to give a fair idea

of the various results obtained with sodium nucleinate injections administered as previously described. Aside from the recoveries already noted, one other patient made a late recovery some months after treatment had been discontinued, but she had had a previous remission without treatment. Four other patients improved to some extent. In nine cases no improvement whatever was noted. Of the four cases that underwent a quite complete remission during treatment, two were catatonic and two hebephrenic. The two showing late improvement were catatonic, as was probably the case of Oswald W. (Case IX) who later relapsed. The six who showed more or less improvement were of types varying from simple hebephrenia to those of a more complicated character.

The writer is not prepared to generalize from the above results. If anything can be said for this treatment, it is that in certain cases it *seemed* to precipitate an improvement which very possibly might have occurred later on without treatment. The treatment certainly does no harm, and may be tried out until definite statistical results are obtained.

SYPHILIS INEXPLICABLE.

BY WALTER S. REYNOLDS, M.D.

NEW YORK.

THE inexplicable vagaries of syphilitic infection are well known. They are well illustrated in a case that recently came under my observation, and for this reason, together with the fact that it may be of service in teaching us lessons of the greatest importance regarding the treatment of the disease, I have deemed it worthy of briefly reporting.

A man 27 years of age was referred to me in July, 1915, with the following history: In 1907 while serving in the navy he contracted a lesion on the penis. He was treated by the naval surgeon who said "it did not amount to much." He was advised to keep it clean, using peroxide of hydrogen as a wash. It became steadily worse and after much pleading he was admitted to the hospital. He was then told that he had a "chancre" and for three months he received treatment by mercury pills. The lesion eventually healed and as his time of service had now expired he was discharged. When leaving he was told that he "was all right now." No further treatment was advised nor was anything said in regard to the nature of his trouble except what was told him at first—that he had a chancre. He returned to his home and in 1914 married, supposing himself perfectly well as he had had no symptoms whatsoever of his former trouble. Three or four months after he married an ulcer on his leg developed for which he was treated by a physician who inquired if he had ever had syphilis. The man explained that he had had an ulcer of the penis and the other circumstances concerning his trouble in 1907. An ointment was used on the leg but no further advice or medication was given him. The ulcer gradually decreased in size but was not entirely healed when I saw him. Four or five weeks before I saw him he began to have sores in his mouth which would improve somewhat when he would stop smoking for a time, but gradually became worse so that he was compelled to seek advice, and the nature of his trouble being recognized, he was sent to me.

The examination showed a well nourished, robust man. On the right leg was a cicatrix about four inches in diameter in the center of which was a crusted rupia-like lesion about an inch in size. There were no other signs of lesions on the body. The tonsils and mucous membrane of the mouth were covered with mucous patches making deglutition and swallowing difficult. The nature of his trouble was made clear to him, and, the probability of his wife having been infected being explained, it was arranged that I should see her as soon as possible. He was quite positive in his statement that he had never known the nature of his trouble and that he was told that he was "all right" on his dis-

charge from the navy. Treatment was immediately begun with neosalvarsan, mercury ointment for the ulcer, and inunctions of mercurial ointment, with nitrate of silver applications for the mucous patches, and the stopping of smoking. Within two weeks all the lesions were entirely healed.

The examination of his wife showed no evidence of infection. The Wassermann was negative at this time, as it was when taken one month later.

Some of the important points which may be brought out are the following: A man after three months' treatment with mercury pills is told that he is well; seven years later he marries, and within a short time develops severe manifestations of syphilis, having had no signs of trouble since his discharge from the navy, seven years previously. It is evident, as I have had occasion to point out before, that too much care cannot be taken in explaining to patients the nature of their trouble. A chancre may mean almost anything to most patients. To have sent this man out after three months of treatment with pills with the statement that he was "all right now" hardly seems credible. And yet I believe the man's statement was true.

That his wife should have escaped infection seems beyond belief, for we know that the saliva of such patients is swarming with spirochetes, and as he had no reason to think there was any danger of infection no precautions were taken against his wife becoming infected. As a result of all this they separated, temporarily at least, although I explained that the danger of infection was not great, provided they lived as I recommended.

132 WEST SEVENTY-THIRD STREET.

A STUDY OF THE DIAGNOSTIC VALUE OF THE RUSSO REACTION.

BY MAX KAHN, M.D., PH.D.

NEW YORK,

AND

LAWRENCE WECHSLER, M.D.,

PITTSBURGH.

IN 1905, Russo described a test which he thought was diagnostic of typhoid fever. As this test has not attained to the general vogue of the Ehrlich diazo reaction has attained, we thought it advisable to study this reaction in various diseases and to compare it with the diazo reaction of Ehrlich and the Weiss urochromogen reaction.

Two years ago one of us¹ reported before the Columbia University Biochemical Association in the form of a preliminary communication his findings with this test. We now wish to dwell somewhat more extensively on this reaction and to compare it with the other urinary tests mentioned above.

The technique of the Russo test is very simple and is as follows: The reagent consists of a 0.1 per cent. aqueous solution of methylene blue. Several drops of this reagent are added to a few cubic centimeters of urine. A positive reaction is characterized by the fact that the urine assumes a mint-green or emerald-green color. If any trace of a bluish tint is present the reaction is negative. This distinction of color must be strictly adhered to for the proper conduction of the test. In order to obviate possibilities of error we compared the color obtained with tinted pieces of glass. We found this to be a very great aid in distinguishing doubt-

(From the Biochemical Laboratories of the Beth Israel Hospital, New York City, and the Western Pennsylvania Hospital, Pittsburgh, Pa.)

ful hues of blue from the true green color. The positive reaction is not affected by boiling the urine, or by the previous ingestion of such substances as phenacetin, salol, quinine, and calomel.

The performance of the Ehrlich diazo reaction is so much in vogue that we shall not describe it, but we shall say a few words regarding the urochromogen reaction of Weiss.

To perform the latter test a reagent is made which consists of a 1.0 per cent. watery solution of potassium permanganate. The urine is now diluted four or five times with water (if the urine is very highly colored it is diluted still further) and to it are added several drops of the permanganate solution. A positive reaction is indicated when the urine assumes a distinct yellowish color, which should not be mistaken for a pink or a light red color.

For the performance of these tests it is absolutely necessary to have daylight, and to be very careful in reading the various hues. With a little experience the tests are very easily carried out.

Webster,² in his text book, states that a positive Russo reaction is obtained, in addition to typhoid fever, in measles, smallpox, chronic and suppurative tuberculosis; but it is negative in varioloid, varicella, scarlet fever, miliary tuberculosis, appendicitis, and malaria.

Rolph and Nelson have pointed out that urines containing bilirubin react to this test, so that this fallacy must be borne in mind.³

We have examined altogether a series of 758 urines from as many patients. In this number of cases there were included many of the acute infectious diseases, chronic infectious diseases, and constitutional and organic affections. The following table will give the number of the cases of each disease studied and the incidence of the various tests in each disease.

Diagnosis	No. Cases	RUSSO TEST		DIAZO TEST		WEISS TEST	
		+	-	+	-	+	-
Typhoid	53	31	22	29	24	2	51
Dysentery	38	7	31	1	40	0	41
Typhus	11	1	10	0	11	3	8
Influenza	9	0	9	0	9	1	8
Rheumatism	26	1	25	0	26	0	26
Diphtheria	9	0	9	0	9	1	8
Measles	16	1	15	3	13	2	14
Erysipelas	5	1	4	0	5	0	5
Tuberculosis	109	10	92	7	95	4	98
Syphilis	81	0	81	0	81	1	80
Erysipelas	6	4	2	1	5	0	6
Dysentery	57	1	56	0	57	8	49
Cancer	63	0	63	1	62	4	59
Exanthematous fever	2	0	2	0	2	0	2
Anemia	7	1	6	0	7	3	5
Leukemia	2	0	2	1	1	2	0
Hemophilia	2	1	1	0	2	1	1
Bant's disease	1	0	1	0	1	0	1
Arteriosclerosis	5	0	5	0	5	1	4
Cardiac diseases	27	0	27	0	27	2	25
Kidney diseases	5	0	35	0	35	2	33
Gastrointestinal diseases	27	0	27	1	26	2	25
Cholera	31	1	30	0	31	4	27
Cholera	11	1	13	0	14	4	10
Renal disease	8	0	8	0	8	1	7
Diabetes	1	0	1	0	1	0	1
Prognosis	14	0	14	0	14	1	13
Subtotal	115	18	97	1	114	2	113

In most cases of typhoid fever the reaction of Russo appears toward the end of the first week and persists even through convalescence. The incidence of this test in typical cases of typhoid fever is in about 60 per cent. of the cases, equalling the incidence of the positive diazo reaction in this disease. Positive Russo reaction has been obtained by us in about 10 per cent. of cases of tuberculosis, even a

higher ratio of positive findings than with the diazo reaction in this condition. So that the statement current that we can differentiate miliary tuberculosis from typhoid fever by the Russo reaction, which is supposed to be negative in tuberculosis and positive in typhoid, is not proven. It is curious to observe that in cases of fractures or such surgical conditions which involve the exudation and absorption of large blood clots, etc., we obtained positive Russo tests in 18 out of 115 cases. In these conditions both the diazo and the Weiss reactions are almost all negative. It will be observed by glancing at the accompanying table that positive Russo reactions were obtained occasionally in quite a number of the various diseases studied, especially in pneumonia, empyema, and certain of the anemias. In a total of 758 cases we obtained 79 positive Russo tests. The Weiss test seems to be entirely inconstant in any disease and is in our opinion of doubtful value.

It seems advisable to adopt the Russo reaction for routine work in the usual clinical laboratory. A positive Russo and diazo reaction in the same urine should have some weight in the clinician's mind in making his diagnosis.

In conclusion we wish to thank Mrs. Rahil Wattan Kahn for having performed most of these examinations.

Medicolegal Notes.

Practising without License.—The Kansas City Court of Appeals holds that the offense created by the Missouri Rev. St., 1909, Sec. 8315, punishing any person practising medicine without a license from the State Board of Health, and the offense created by Sec. 8314 punishing any person holding a license who neglects to record it in the county of his residence, are separate and distinct offenses and should not be charged in one count. —State vs. Huxoll (Mo.) 178 S. W. 866.

Retroflexion of the Uterus—Probable Causes.—Action was brought against a street-railway company for an injury sustained as a result of a collision between two of the defendant's cars, which it was claimed caused a retroflexion of the uterus. Upon the first crash of the collision the plaintiff jumped up. The second crash threw her back onto the seat. The retroflexion was discovered by her physician six weeks after the accident. One of the defendant's physicians, who had examined her within thirty-six hours after the accident, testified to finding no evidence of pelvic disturbance or conditions indicating that a retroflexion of the uterus was present. Other witnesses for the defendant testified that her condition was the result of overwork, lack of sufficient nourishment and anemia, and that retroflexion of the uterus could not result from an injury unless the injury was of a severe crushing or piercing character; that the condition of retroflexion is usually the result of a gradual wearing down of the ligaments supporting that organ, and that it frequently occurs among overworked, overtired, under-nourished, and generally anemic women.

The plaintiff testified that prior to the accident she had been in good health, and her physician's testimony was to the effect that the condition of retroflexion found on his examination made six weeks or two months after the accident was due to some external violence, and that such violence so weakened the uterine structure that the uterus prolapsed; and further that there was a relation between the condition of the plaintiff at the time of the trial and the accident in question. The evidence was held sufficient to present a question for the jury as to whether the accident was the proximate cause of the condition found as against the defendant's claim that the condition was the result of natural causes.—Murphy vs. Chicago City R. Co. 191 Ill. App. 431.

New York, January 15, 1916.

REPORT OF THE SURGEON GENERAL OF THE UNITED STATES ARMY.

THE report of the Surgeon General of the United States Army for the calendar year 1914 has just been issued. The report is a lengthy and, from the scientific and public health standpoints, an extremely interesting document. The mean enlisted strength of the army for the year under review, as reported on the monthly sick report of the Medical Department, was 87,228. During the year 1914 American troops were stationed in the United States proper, the Philippine Islands, China, Alaska, Hawaii, and the Canal Zone. During 1914 the admissions to sick report show a satisfactory decrease. The rate is 665.83. The admission rate for disease only is 539.46. The 1914 rate is the lowest ever reached in the history of the army. The highest admission rates were caused by the following diseases, named in their order of prevalence: venereal, 110.69; diseases of the pharynx, 56.96; bronchitis, 33.83; diarrhea and enteritis, 31.39; malarial, 20.07. For venereal diseases the rate for white troops was 109.48; for colored, 128.70. The rate in the Philippines, for these troops, were 174.79 and 233.76, respectively. As pointed out in the report, these high rates are due to local social conditions and indicate that radical changes in these conditions must be brought about ere rates comparable to those in the United States may obtain. Measures already introduced have effected a great reduction of the rates for venereal diseases in the Philippines, and, therefore, further progress in the direction of checking these diseases may be hopefully anticipated.

The noneffective rate is the true criterion of the nonefficiency of an army from sickness and injury. Judged from this angle, the condition of the United States Army for 1914 was satisfactory, for the rate for that year was the lowest recorded noneffective rate in the history of the army.

The total death rate for American troops for 1914 was 4.45, which is a low record for the army. The death rate from disease for the United States enlisted men was 2.52 per 1,000. That from external causes was 2.30. The total from diseases and external causes was 4.82. Tuberculosis caused 29 deaths; measles, 8; lobar pneumonia, 15, and cancer, 6.

With regard to the prevalence of special disease, there were seven cases of typhoid fever during the year in the army stationed within the geographical limits of the United States. In connection with this disease it is interesting to mention that among all the troops scattered along the Mexican border and in the large camps in Texas not a single case of typhoid fever has occurred in an inoculated man since June 4, 1912.

Again reverting to the venereal disease scourge, according to the report, it is believed that the instruction of soldiers as to the dangers arising from the malady is inadequate. An intelligent and comprehensive service of lectures should be given at recruit depots on hygienic matters, including venereal diseases. This instruction should be aided by illustrations and moving pictures adapted to the subject. This mode of instruction should be kept up at posts and should include questions of general interest in military sanitation. This system is to be recommended when certain details have been determined.

The admission rate for alcoholism in the United States Army for the year 1914 was 13.46, which is lower than the preceding year, when it was 14.24. Since 1907 the rate has shown a steady diminution. No marked improvement in the health of the American troops stationed in the Philippines was exhibited during the year 1914 as compared with 1913. The higher rate for venereal diseases is, in particular, a matter of great concern. The admission rate for all fevers of the malarial class was considerably less.

VISUAL EFFICIENCY.

As the most dignified of the senses—"the five gateways to the soul"—it is little wonder that so much attention is now being riveted on the conservation of vision either from the standpoint of preventable disease, defect, or blindness, or, and especially, from the standpoint of visual acuity, of visual efficiency, in otherwise disease-free eyes. While the element of heredity enters into the development of visual defects in perhaps 10 per cent. of the cases, it is generally conceded that the bulk of the visual conditions are environmental, that is, industrial or educational in origin. On the other hand, it seems that the diminution of visual acuity is either a necessary outcome of the occupational, educational, and living tendencies of modern times, or else the increase is only apparent and not real and brought about by the refinements in diagnosis. The question of the efficiency of the eyes comes into more relief as there is greater intensity in the use of them. Aboriginal races, such as the American Indian or the Esquimo, have always been thought to have vastly more acute vision than modern races. In countries of the highest scientific development upward of 60 per cent. of the population suffer with visual defects. In certain occupations upward of 75 per cent. of the individuals thus engaged were found to suffer with visual defects (Bulletin 71, Hygienic Laboratory, U. S. P. H. S.). In all likelihood, however, the great visual acuity attributed to aborigi-

nal races is not due to a physical-sense superiority, but rather to their great ability in interpreting what they see. They have larger visual capacity though not greater visual acuity. Very near-sighted people may often recognize indistinct objects better than the farsighted, because put to the necessity of learning to interpret. Visual perception is not in proportion to the strength of the physical sensation, but is a judgment derived, as are all judgments, from other senses, previous visual perceptions, and experiences. A great variety of sensations rather than greater visual strength leads to greater capacity.

Even the most meager inquiry into the matter of visual acuity reveals how little is known as to the extent of vision of the farsighted and still less of the nearsighted. Nor, in view of the necessity of doing all of the finer works at the visual near point, is it possible to say which of the two forms of vision is the more desirable. We do not know how much ultimate loss of efficiency there is from one-eyed vision. Binocular vision permits a greater field to come before the retina at one time, but there is no greater acuity than in one-eyed vision. Indeed, if there is required a greater intensity in a given field, it is a natural tendency to obscure the vision of one eye.

The standard test type for determining visual acuity takes no cognizance of the actual minimum visual requirements in the various fields of endeavor, although it does purport to set out a general minimum. In transportation occupations the maximum amount of distant vision is almost absolutely necessary. Any appreciable reduction of vision in this respect, even of the kind that occurs in later life, is fatal to this occupation. On the other hand, the greater the acuity for distance the more difficulty there is in accommodating constantly to near work, and most of the eyestrain comes from trying to harness the farsighted to near work. Certain occupations almost demand nearsighted vision. The nearsighted, for example, are particularly fitted, because of their power of magnification, for such work as is exemplified by the engraving occupations.

If the test-type criterion is applied as a uniform test of visual efficiency, certain individuals with a low distant acuity will be barred from occupations for which they are, perhaps, peculiarly fitted, while certain others may be admitted on the strength of these tests into occupations for which they are not fitted particularly, because of their high acuity for distance. In determining visual efficiency, tests must not be made in the abstract but in relation to definite occupations. Almost no amount of nearsight, except perhaps in those pathological conditions found in extreme myopia with posterior staphyloma, bars one from work requiring near application. While correction of refractive errors is absolutely essential for comfort, to increase acuity, and especially to prevent greater defect, very few high defectives, particularly myopes, can get anywhere near a full correction. There is, however, no mathematical relation between distant and near vision. Near vision may be corrected to the recognized 'normal, while in the same individual

the distant vision will hardly be affected. A great many misfits can be prevented by determining the kind of occupation the individual will be best fitted for. In the last analysis it should be the aim to educate the vision one has to greater powers by calling to aid all sources of orientation—to educate and train visual perception so that one may perceive more of the objects within the field of one's vision.

DRUG ADDICTION IN THE UNITED STATES.

THE newspapers of the country, and especially the more sensational ones, are responsible in a great measure for the growing belief that the number of those addicted to the harmful use of drugs in America is so widespread as to be a national menace. Lurid and wild statements on this subject are too frequently published, and while it is well that the facts should be as nearly as possible known and made public, it is contrary to the best interests of the community at large that misleading assertions should be put forward.

Martin I. Wilbert presented a paper dealing with the matter at the meeting of the Pennsylvania Pharmaceutical Association held at Forest Park, Pa., June 22-24, 1915, which was published in the Public Health Reports, Aug. 6, 1915. It is pointed out in this paper that most of the statements made are not based upon reliable data, and while it is not denied that the number of drug addicts in this country is disgracefully large, it does not, and obviously cannot, even approximate the maximum that has been asserted.

Perhaps the most instructive part of the paper referred to is that which relates to the origin of the drug habit. C. E. Terry of Jacksonville, Fla., in the report of a study of local conditions, published in the *American Journal of Public Health*, 1914, v. iv., p. 32, states that 213 cases of drug habituation studied by him personally, their origins in the order of their frequency were as follows: Through physicians' prescriptions or treatment personally administered, 54.6 per cent.; through the advice of acquaintances, 21.6 per cent.; through dissipation and the example of evil companions, 21.2 per cent.; through chronic and incurable disease, 2.4 per cent.

The conclusions reached by Terry that from 90 to 95 per cent. of the persons using narcotics habitually do so in a wholly unnecessary manner is in agreement with those come to by Brown, and probably by the majority of observers. Wilbert concludes that, "To secure efficient restrictions on the sale and distribution of narcotics, and to demonstrate that they are not primarily to blame for the generation and continuation of the addiction referred to, pharmacists individually should not alone be willing to comply with existing requirements under the law, but should see to it that others engaged in the same line of business comply fully with the spirit as well as the letter of existing laws and regulations." The Federal antinarcotic law may aid in solving the problem, though it has not yet demonstrated its value in this or any other direction.

THE WIDAL REACTION IN TUBERCULOUS PERSONS.

IN the application of the results of the Widal reaction in diagnosis it has been the custom to warn the clinician that he must be especially careful to exclude the possibility of tuberculosis since a certain percentage of tuberculous persons will give a positive Widal. This custom is based upon a number of observations made by reliable investigators and clinicians and has found, for the most part, ready acceptance. There has been no satisfactory explanation of this phenomenon yet proposed and it has always seemed curious that a reaction as specific as the agglutination test should be positive in infections due to such widely differing organisms. The problem has attracted the attention of several investigators, some of whom have been successful in finding the typhoid bacillus in the stools of tuberculous patients who had positive Widal. Chesley and Wade have had access to a large amount of material drawn both from private practice and from sanatoria. They report (Trans. Natl. Assn. Study and Prev. Tuberc., 1915, page 250) the examination of blood from 1,017 patients suffering from tuberculosis. In nearly all the cases the examination of the sputum revealed the presence of tubercle bacilli, while in the others the patients were residents of tuberculosis sanatoria and the diagnosis was accepted as correct. Of these cases 28, or 2.7 per cent., showed a positive Widal in dilutions of 1:50 or over, while 7 gave a partial reaction. Circumstances were such that the authors were able to pursue their investigations in only eleven of these cases. In seven of them the *B. typhosus* or *B. paratyphosus* was isolated from the urine or feces. In the other four cases the attempts to isolate similar organisms have as yet been unsuccessful, due, the authors believe, either to the difficulty of securing specimens or to an insufficient number of examinations. This is very significant work for it clears up a point which has been more or less of a stumbling block in diagnosis and does it very decisively. The authors' concluding words seem to be amply justified by the evidence: "It appears that there is little reason for believing that the Widal reaction in the tuberculous indicates anything short of present or recent infection with members of the typhoid group."

AN EPIDEMIC OF THE "FOURTH DISEASE."

VERY little is heard nowadays of the so-called "fourth disease," described by Filatow in 1885, and by Dukes in 1900. There is no consensus of opinion as to the exact nature of this condition, some writers regarding it as a distinct clinical entity occupying a position intermediate between scarlet fever and röteln, other writers characterizing it as a mild type of scarlet fever. An epidemic of about one hundred cases of the "fourth disease" was observed by Diego Guigo y Costa (*La Pediatría Española*, August 15, 1915), on the island of Tenerife from February to July, 1914, the maximum incidence occurring during May. The clinical aspect of the cases corresponded to that described by Dukes, with certain modifications probably dependent upon the differences of climate. The eruption was more marked in adults than in children, but there were fifteen children affected to every one adult. A cervical polyadenitis was a constant phenomenon, but the enlarged glands were perceptible only to the touch. A slight albuminuria was observed during

the febrile period and not as a late manifestation as occurs in scarlet fever. The incubation period varied between seven and thirteen days. In some instances there was distinct evidence that the disease was carried by a third person.

News of the Week.

Federal Quarantine for New York.—A Washington dispatch, dated January 12, brings the gratifying announcement that the New York quarantine station is to be placed at once under Federal control. The transfer is a temporary one, made at the suggestion of Governor Whitman, to continue until the New York Legislature can take the necessary steps to make it permanent. Surgeon General Blue has detailed Dr. L. E. Cofer of the Public Health Service to take over the station. At a meeting of the New York Academy of Medicine four years ago, Dr. Cofer delivered an eloquent and convincing address in advocacy of the national control of the quarantine station at this port, and it is therefore most fitting that he should be the first federal official to be placed in command of the station.

Vital Statistics for 1915.—The Department of Health reports that during the year just closed there were recorded in New York City 76,193 deaths, giving an estimated death rate of 13.61 per thousand of population, which is three-hundredths of a point less than the rate for 1914. Influenza and the acute respiratory diseases showed an immense increase over 1914, causing 12,000 deaths, or 1,500 more than were recorded the previous year. The mortality of these diseases being estimated as 20 per hundred, it is estimated that 60,000 cases occurred during the year. Despite the prevalence of measles during the early part of 1915, the deaths due to contagious diseases decreased by 186, and there was an actual decrease of 94 in deaths due to tuberculosis. The deaths from cancer totaled 186 more than those during the previous year, the mortality from this disease having shown a gradual increase for a number of years past. There were 13,872 deaths among infants under one year of age, an increase of 560 over last year, the infant death rate being 99 as compared with 95 in 1914. The increased mortality was due principally to gastroenteritis, measles, and pneumonia. During the year 141,356 births were reported, giving a rate of 25.56, as compared with 140,642 births, and a rate of 25.65 for 1914. The marriage rate also was lower in 1915 than in 1914, 9.11 as compared with 9.67, the total number of marriages reported being 50,998 and 53,052. The decrease in the birth and marriage rates is attributed to the financial depression and the decrease in immigration because of the war.

The Epidemic of Grip.—The mortality from the epidemic of grip which seems to be widely spread throughout the country was very heavy during the last week of 1915 and the first of 1916, in New York City alone 375 deaths being ascribed to pneumonia during the last week of the year, as compared with 85 during the first week of November. The number of cases of pneumonia during the week was estimated at not less than 2,000. The research laboratory of the department is carrying on a bacteriological investigation to determine the exact nature of the infection. Chicago reported 1,112 deaths from grip and pneumonia during the last week of December, breaking all previous records; in Denver 100 deaths during the month were ascribed to

these two causes, and in Ann Arbor, Mich., the surgical work of the University Hospital was, it is reported, brought to a standstill because of the prevalence of grip and pneumonia among the nurses. It was hoped that the clear, cold weather prevailing during the second week of the year would greatly improve conditions. In New York City the health commissioner has requested the cooperation of the police commissioner in a vigorous enforcement of the section of the sanitary code covering the filthy and unsanitary habit of spitting in public places.

To Protect Watershed.—In his annual message to the New York Legislature regarding the State budget, Governor Whitman says: "I have included no appropriation either for the Mohansic Hospital for the Insane or the New York State Training School for Boys at Yorktown Heights in the tentative budget proposal, and I recommend that the construction of these institutions be abandoned, in view of the opposition of the City of New York toward the continuance of them on the Croton watershed. Pending a decision on this matter I have ordered work on all contracts in connection with these two institutions stopped. To meet the problem of relieving the congestion in the insane hospitals in the metropolitan districts, I recommend the construction of buildings for the care of the aged insane, of which there are a large number in our State hospitals, first at Middletown, and elsewhere as the necessity presents itself."

Fire in Hospital.—A small fire in some soiled linen at the bottom of a clothes chute in the Metropolitan Hospital on Blackwell's Island, New York, on January 5, was extinguished without serious damage.

Gifts to Columbia.—At a meeting of the Trustees of Columbia University on January 3, the following gifts were announced: \$75,000 from Mrs. William Douglas Sloane, to be added to the endowment of the Sloane Hospital for Women; \$1,000 from Mrs. Emily Ladenburg, to be applied toward the medical school removal and rebuilding fund, and \$400 from an anonymous donor for salaries in the department of the practice of medicine.

China Medical Board.—The members of the China Medical Board of the Rockefeller Foundation, who sailed from San Francisco last August for China, to arrange for the reorganization of the Union Medical College at Peking, have returned to this country much pleased with the reception accorded them. The board was composed of Dr. William H. Welch of Johns Hopkins University, Dr. Simon Flexner of the Rockefeller Institute, and Dr. Wallace Buttrick, secretary of the General Education Board. The board reached the conclusion that the school should be reestablished on the highest plane, and have under consideration an invitation to establish another medical school at Shanghai, to take the places of the medical school of St. John's University, the Harvard Medical school, and the medical school of Nankin University. Nearly thirty medical schools in China were visited by the board, as well as the imperial universities at Tokio and Kyoto, Japan, and the Union Medical College at Seoul, Corea. At Changsha, China, where the Hunan Yale Medical School has recently been established, Dr. Welch laid the cornerstone of the new hospital building, which is to cost \$200,000.

An Aerial Ambulance.—The use of aeroplanes as ambulances by the French Army during the recent retreat from Serbia has been reported. A

number of wounded soldiers were just behind the line of retreat, it is said, and it was found impossible to carry them on stretchers. Six aeroplanes were thereupon pressed into service and the transfer was successfully accomplished.

Health Department Pharmacy Closed.—The drug laboratory and pharmacy of the New York City Department of Health passed out of existence on January 1, its functions being transferred to the general drug department of the Department of Charities. The laboratory was abolished for the sake of economy after a long controversy between the Health Department and the Department of Charities.

Typhus in Mexico.—Recent reports from Mexico indicate that the present situation there in regard to typhus fever rivals that of Serbia last year. It is said that in Mexico City alone during December there were 30,000 to 50,000 cases of the disease, and that the Mexican Government having refused outside help is endeavoring to suppress the facts.

Recognition of Nurse's Services.—The Medical Board of the Willard Parker and Riverside Hospitals at a recent meeting adopted resolutions in honor of the devotion to duty of Miss Katherine B. Holden, for nearly thirty years a nurse in the Department of Health, whose death occurred on December 7.

Industrial Insurance.—The American Medical Association has recently appointed a committee to cooperate with the American Association for Labor Legislation in drafting a model bill for the establishment of industrial insurance in each State. The committee consists of Dr. Alexander Lambert, New York, Dr. H. B. Favill, Chicago, and Dr. Frederic J. Cotton, Boston.

Hospital Unit in Berlin.—The hospital unit sent out recently by the American Physicians' Expedition Committee under the charge of Dr. Frederic Kammerer of New York, reached Berlin on January 4. The unit will be given charge of the military reserve lazaret at Deutsch-Eylou, East Prussia.

Drug Raid.—Large quantities of cocaine and heroin were captured in a raid made on an apartment house in East Nineteenth Street, New York, on January 3, and three prisoners, said to be members of a large operating gang, were taken.

Personals.—Dr. GEORGE L. WALLACE of Wrentham, Mass., has been asked by the Commissioner of Charities to become superintendent of the New York City Children's Hospital and Schools on Randall's Island.

Surgeon General RUPERT BLUE of the U. S. Public Health Service has been renominated by President Wilson for another term of four years.

Major General GORGAS at a banquet in Chicago on January 8 was presented with the gold medal of the Geographic Society of Chicago, for his distinguished services to humanity. Only twice before has this medal been awarded, once to Captain Amundsen and once to General Goethals.

Dr. JOHN F. ANDERSON, formerly director of the hygienic laboratory of the U. S. Public Health Service, has resigned to take charge of the Squibb Research and Biological Laboratories. He is now in Europe studying the methods in use in the French and English armies for the prevention and treatment of wound infections.

The de Roaldes Prize.—Dr. D. Byron Delavan, chairman of the prize committee, announces that the de Roaldes prize, a gold medal, of the value of

\$100, the object of which is to encourage the advancement of the sciences of laryngology and rhinology, is now open for competition to practitioners in regular standing in the United States and Canada, not members of the American Laryngological Association. Essays must be typewritten, the customary means being taken to prevent disclosure of the author's name. They must be placed in the hands of the secretary of the association, Dr. Harmon Smith, 44 West 49th Street, New York, prior to April 20, 1916.

Harvey Society.—The fifth lecture of the series will be given at the New York Academy of Medicine on Saturday evening, January 15, 1916, at 8.30 P. M. by Dr. Donald D. Van Slyke, his subject being "The Present Significance of the Amino Acids in Physiology and Pathology."

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7018 Jenkins Arcade Building, Pittsburgh, reports the following contributions for the two weeks ending January 8:

Dr. W. C. Cahall, Philadelphia, Pa. (second contribution)	\$1.00
Dr. D. S. Lamb, Washington, D. C.	5.00
Receipts for the two weeks ending Jan. 8	\$6.00
Previously reported receipts	7,930.86
Total receipts	\$7,936.86
Previously reported disbursements:	
1,625 standard boxes of food at \$2.20	\$3,575.00
1,274 standard boxes of food at \$2.30	2,930.20
333 standard boxes of food at \$2.28	761.81
Total disbursements	7,210.91
Balance	\$626.82

Medical Society Elections.—MEDICAL SOCIETY OF THE COUNTY OF HERKIMER (N. Y.): Annual meeting on December 7. Officers elected: *President*, Dr. James W. Graves, Herkimer; *Vice-Presidents*, Dr. Charles J. Diss, Ilion; Dr. William P. Earl, Little Falls; Dr. U. G. Williams, Newport; *Secretary*, Dr. A. Walter Suiter, Herkimer; *Treasurer*, Dr. George W. Graves, Herkimer.

MEDICAL SOCIETY OF SOUTH CAROLINA: At the 126th anniversary meeting of this society held at the Roper Hospital, Charleston, a portrait of Dr. Samuel Wilson, one of the early presidents of the society and founder of its medical library, was presented by the faculty of the Medical College of the State of South Carolina to the society. The following officers were elected: *President*, Dr. Lane Mullally, Charleston; *Vice-President*, Dr. Edward Rutledge, Charleston; *Secretary*, Dr. Albert Mathau, Charleston; *Treasurer*, Dr. D. L. Maguire, Charleston.

SEDGWICK COUNTY (KAN.) MEDICAL SOCIETY: The following officers were elected at the annual meeting held on December 21 at Wichita: *President*, Dr. J. Gray Dorsey, Wichita; *Vice-President*, Dr. Martin Hagan, Wichita; *Secretary-Treasurer*, Dr. Edward D. Kilbourne, Wichita.

JEFFERSON COUNTY (KY.) MEDICAL SOCIETY: Annual meeting at Louisville on December 20. Officers elected: *President*, Dr. J. Garland Sherrill, Louisville; *Vice-Presidents*, Dr. B. J. O'Connor, Louisville, and Dr. Oscar E. Bloch, Louisville; *Secretary*, Dr. E. O. Grant; *Treasurer*, Dr. Albro L. Parsons, Louisville.

PUEBLO CLINICAL AND PATHOLOGICAL SOCIETY: Under this title the physicians of Pueblo, Col., organized a new society recently with the following officers: *President*, Dr. Crum Epler; *Vice-President*, Dr. Elmer A. Elder; *Secretary-Treasurer*, Dr. D. E. Hoag; *Historian*, Dr. Fred Heller.

CALDWELL COUNTY (KY.) MEDICAL SOCIETY: An-

nual meeting at Princeton on December 17. Officers elected: *President*, Dr. J. M. Moore, Princeton; *Vice-President*, Dr. W. P. Morse, Princeton; *Secretary-Treasurer*, Dr. W. L. Cash, Princeton.

SEVENTH DISTRICT (S. D.) MEDICAL ASSOCIATION: At the annual meeting held at Sioux Falls on December 16, the following officers were elected: *President*, Dr. E. L. Perkins, Sioux Falls; *Vice-President*, Dr. H. R. Hummer, Canton; *Secretary-Treasurer*, Dr. G. Zimmermann, Sioux Falls.

BASTROP COUNTY (TEX.) MEDICAL SOCIETY: Annual meeting at Bastrop on December 17. Officers elected: *President*, Dr. F. J. Kroulik, Smithville; *Vice-President*, Dr. N. B. Harris, Red Rock; *Secretary-Treasurer*, Dr. Carter.

GRAFTON COUNTY (N. H.) MEDICAL SOCIETY: Twelfth annual meeting at Woodsville on December 14. Officers elected: *President*, Dr. Elmer M. Miller, Woodsville; *Vice-President*, Dr. Percy Bartlett, Hanover; *Secretary-Treasurer*, Dr. George A. Weaver, Warren.

The Late Dr. A. A. Smith.—The following minute was adopted by the Medical Board of Bellevue Hospital at its meeting held on January 3, 1916:

"Dr. A. Alexander Smith, whose death in the sixty-ninth year of his age occurred suddenly on December 13, 1915, had, for thirty-three years, been a member of the Medical Board of Bellevue Hospital, and for the greater part of that time on its executive committee. The genial quality of his temperament and his abounding faith in his fellows made of Dr. Smith a peculiarly lovable man, endearing him to all with whom he came in contact, but lessening in no wise the forcefulness of his character. He was instant in service, and gave to the poor and needy of his best; not mere outward service, but that supported by strong sympathy and deep religious conviction. Apparently enjoying the best of health he continued his work actively until almost the very day of his death, and it came as a distinct shock to his colleagues to learn that the silver cord of his life had been loosed, the golden bowl broken. This minute is to record the sorrow of the medical board, their sense of profound loss, and to express their sympathy with the surviving relatives."

The Late Dr. Francis Delafield.—The New York Pathological Society at its meeting December 8, 1915, adopted the following minute:

"Dr. Delafield became a member of the society in 1867, and was its president in 1875. For many years he gave his active and consistent support to all the interests of the society. At its meetings he presented the results of much of his early pathological work and gave evidence of that remarkable genius for careful observation and sound interpretation of pathological processes, which formed the foundation stone of his great eminence in medicine. Dr. Delafield left a permanent impress on the science of pathology. His researches on the pathological anatomy of the kidneys and the lungs were epoch making and they formed the basis of a system of pathology peculiarly his own. It was his constant endeavor to correlate clinical medicine with the lesions found after death. He devised technical methods which received world-wide adoption. His conception of inflammation has been recognized as both profound and practical. His 'Studies on Pathological Anatomy' established a standard rarely attained, and will always remain classic. He was not only a thoroughly versed morphologist, but a pathological physiologist as well. Although a highly skilled technician he prepared

beautiful gross and microscopical specimens for the chief purpose of gaining a deeper insight into the pathogenesis of lesions and symptoms. Having applied this method of study over a wide range of medicine he became a master in the interpretation of clinical phenomena. He thus became a truly great clinician. No one has had a greater and more wholesome influence on the theory and practice of medicine in this country than Dr. Delafield. The retrospect of his carefully planned and well rounded career reveals a model of deliberate preparation and logical attainment which leaves a permanent influence upon the host of pupils, colleagues, and personal friends, and upon the entire American medical profession. The Pathological Society recognizes in his loss the passing of one of its most valued members and one of the great lights of the medical profession."

Obituary Notes.—Dr. ARTHUR L. REEVE of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1896, died at his home on January 4.

Dr. EDWARD C. KROOS of Brooklyn, N. Y., a graduate of the New York University Medical College, New York, in 1892, and a member of the American Medical Association, the New York State and Kings County Medical Societies, and the Brooklyn Medical Society, died at his home on December 30, aged 53 years.

Dr. DAVID L. DEAL of Pacific Grove, Cal., a graduate of the Cooper Medical College, San Francisco, in 1864, died at his home on December 14, aged 73 years.

Dr. DENIS F. RAGAN of San Francisco, a graduate of the Cooper Medical College, San Francisco, in 1887, and a member of the American Medical Association, the Medical Society of the State of California, and the San Francisco County Medical Society, died at his home, after a long illness, on December 19, aged 54 years.

Dr. ADOLPHUS M. SCHEEL of Belleville, Ill., a graduate of the University of Munich, Germany, in 1876, and a member of the American Medical Association, the Illinois State and St. Croix County Medical Societies, the Southern Illinois Medical Society, and the Belleville Medical Society, died at his home after a long illness, on December 16, aged 64 years.

Dr. HENRY CLAY FAIRBROTHER of East St. Louis, Ill., a graduate of the Washington University Medical School, St. Louis, in 1872, a veteran of the Civil War, and a member of the American Medical Association and the Illinois State and St. Clair County Medical Societies, died at his home, after several weeks' illness, on December 15, aged 70 years.

Dr. ALFRED A. WEBER of Chicago, Ill., a graduate of the University of Vienna, Austria, in 1885, died suddenly at his home, from heart disease, on December 19, aged 58 years.

Dr. IRA D. PAYNE of Des Moines, Ia., a graduate of the State University of Iowa, College of Medicine, Iowa City, in 1880, and of the Bellevue Hospital Medical College, New York, in 1886, died suddenly at his home on December 11, aged 63 years.

Dr. FALK TENNYSON of Minneapolis, Minn., a graduate of the University of Minnesota, Minneapolis, in 1893, and a member of the Minnesota State Medical Association and the Hennepin County Medical Society, died at his home from meningitis, on December 17, aged 48 years.

Dr. HENRY LAURENS METCALF of Natchez, Miss., a graduate of the Tulane University of Louisiana,

School of Medicine, New Orleans, in 1878, died at the home of his brother, on December 14, aged 48 years.

Dr. OTTO STUCKERT of Whiteside, Mo., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1890, died on December 20, aged 53 years.

Dr. JOHN H. KEMP of Philadelphia, Pa., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1900, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Philadelphia County Medical Society, died at his home on December 14, aged 36 years.

Dr. WILLARD H. GREENE of Providence, R. I., a graduate of the Jefferson Medical College, Philadelphia, in 1865, a veteran of the Civil War, and a member of the American Medical Association and the Rhode Island and Providence District Medical Societies, died at the Rhode Island Hospital on December 19, aged 83 years.

Dr. WILLIAM A. SWIMLEY of Winchester, Va., a graduate of the Cincinnati College of Medicine and Surgery in 1876, died in the King's Daughters' Hospital, Staunton, Va., on December 18, aged 69 years.

Dr. GEORGE W. ADAMS of Huntington, W. Va., a graduate of the Cincinnati College of Medicine and Surgery in 1889, died at his home, after a long illness, on December 15, aged 64 years.

Obituary.

JAMES CLARKE WHITE, M.D.,
BOSTON, MASS.

DR. JAMES CLARKE WHITE of Boston, emeritus professor of dermatology in the Harvard University Medical School and well known as an author and lecturer, died at his home, after a long illness, on January 6, aged 83 years. Dr. White was graduated from the academic department of Harvard in 1883, and from the medical school three years later. In 1871 he became professor of dermatology in the school, retiring in 1902. He was a member of the American Dermatological Association, of which he was the first president, the Boston Dermatological Club, the Royal Society of Medicine of Great Britain, and the American Academy of Arts and Sciences, and a member and former president of the Massachusetts Medical Society.

ACHILLES ROSE, M.D.,
NEW YORK.

DR. ACHILLES ROSE died on Monday of this week from pneumonia. He was born in Germany in 1839, and after completing his gymnasium course in that country, came to America at the age of 22 years. Here he began the study of medicine, receiving his degree from the College of Physicians and Surgeons in 1872. Dr. Rose devised a number of therapeutic measures which were well received, but he was best known as a champion of philological purity in medical terminology. His interest having been aroused by an editorial article in the MEDICAL RECORD advocating the adoption of Modern Greek as the international language of science, he took up the study of this language and soon became proficient in it. The later years of his life were then devoted to an endeavor to recast the language of medicine in a pure Greek mould, a task which he pursued with zeal and an earnestness of purpose worthy of a less hopeless cause.

Correspondence.

IODINE INTERNALLY IN THE TREATMENT OF ERYSIPELAS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the issue of your excellent journal of December 18, I noticed a short paragraph stating that Magi had gotten some excellent results in painting the affected area of erysipelas with tincture of iodine, etc. I wish to relate a little experience I have had with the internal administration of tincture of iodine in two cases of erysipelas: one of the scalp and the other of the nose.

Some twenty-odd years ago I was practising medicine in a small town and country district. During one autumn I had several cases of erysipelas occurring in the same neighborhood in rapid succession.

One was of the leg, caused by a red hot wagon wheel tire falling against the blacksmith's leg that had an old ulcer, the hot tire striking and burning the ulcer. Erysipelas set in from this burn and the patient died in about ten days. Another case I had about the same time was that of a prosperous merchant about fifty-five years of age. This was of the scalp. I do not recall that there was any wound or abrasion whatever. He was a drinking man, and the onset was with high fever, rapid pulse, and characteristic flushed face and scalp. He also developed an acute alcoholic delirium that was intense for twenty-four hours. The treatment then was after the methods recommended by H. C. Woods in his work on "Therapeutics"—large doses of the tincture of the muriate of iron, with some local application like lead water and tincture of opium. This patient made a long, tedious recovery.

Another case I had about the same time was erysipelas of the scalp in a large muscular colored man about twenty-five years of age. This man lived near the residence of the merchant mentioned above. The fever ran high, the pulse was rapid, and the swelling in the face and scalp was immense; the eyes were completely closed. I was fearful of losing the patient on account of the violence of the attack. I gave him twenty-five drops of tincture of iron every four hours, well diluted with water, in addition to the usual local applications. When the first prescription of tincture of iron had been given I ordered it refilled and to be continued. I saw the negro at nine o'clock one morning, when the prescription was refilled, with the understanding that they continue giving it. I went out of town to attend a case of labor and did not return until the next day. When I got home I found a man waiting for me to go to see the patient again. I asked him how the patient seemed. He replied better, but he felt sure some mistake had been made in refilling the last prescription, and to prove it showed me the medicine. I readily recognized that the druggist had dispensed tincture of iodine in the place of the tincture of iron. I asked the man if the patient had been taking the twenty-five drops every four hours, as he had been taking the former prescription. He said he had. Knowing that twenty-five drops of tincture of iodine was a pretty heroic dose, as three to five drops is a dose usually recommended by medical writers, I went immediately to see results. You can imagine my surprise when I entered the cabin door and found the negro sitting up in bed eating a piece of corn bread and drinking a glass of but-

termilk with great relish. All fever had gone, and the swelling of the face and scalp entirely relieved; in fact, he was a well negro. I asked him how he felt. He said all right, but that the last medicine "shore was stout." He was all right from that time on.

I waited twenty years hoping that fate would throw another case of erysipelas of face or scalp in my way, for I was determined to test the efficacy of iodine again. On the first day of September, 1914, I was appointed superintendent of State Charity Hospital, Jackson, Miss. I had not been in the hospital many days when the assistant surgeon asked me to see a case with him. We readily recognized a case of erysipelas of nose and face. The man, about twenty-five years of age, robust, strong, and muscular had gotten into a street fight, his antagonist biting him through the nose. They were sent to the city jail. A few days afterward erysipelas set up in the bitten nose. The man was sent to the hospital for treatment. I told the assistant surgeon of my former experience and ordered the patient be given twenty-five drops of the tincture of iodine every four hours. In his case, as in the case of the negro the temperature began going down, the swelling of the face and head was relieved. On the fourth day he was discharged from the hospital in good shape.

Of course, I know the remedy has not been sufficiently tested to enable us to reach any definite conclusion, but I believe it worthy a further trial, and merely furnish the above report with the hope that others having a larger field of operation may test it out and give results. L. S. ROGERS, M.D.

JACKSON, MISS.

PROSTATIC TOXEMIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I should like, with your permission, and provided the expression has not been used before, to file a caveat for the term prostatic toxemia. Many physicians must have felt that in many cases of enlarged or congested prostate the symptoms produced were altogether out of proportion to what one would expect, and could only in small part be accounted for by the mechanical obstruction to urination. The severe somatic and psychic symptoms produced by a diseased prostate and the remarkable—one feels occasionally like using the term magical—improvement which often follows one thorough prostatic massage make the conclusion almost inevitable that a toxic substance is produced by the prostate which is absorbed by the blood-current. The term prostatic toxemia, signifying an absorption into the system of a toxic substance generated by an abnormal prostate, is therefore both necessary and appropriate.

1. Foot Strain and Other Common Foot Defects. Hermar W. Marshall.
2. The Prognosis of Incipient Senile Cataract. David W. Wells.
3. The Radical Treatment of Peritonsillar Abscess by Tonsillectomy During the Acute Stage of the Disease. Harry A. Barnes.
4. Notes of Conference on the Medical and Social Aspects of Syphilis of the Nervous System. (Continued.) Harry C. Solomon and Hilmar O. Koefod.

1. Foot Strain and Other Common Foot Defects.—Herman W. Marshall groups these cases into: (1) Simple relaxations and strains. (2) Rigid flatfoot and allied conditions. (3) Foot strain accompanying other distinct pathological states. (4) Miscellaneous lesions confused or associated with foot strain. After discussing each of these groups he concludes that one should avoid the use of any single special method of treatment. In simple relaxations and strains, or in rigid flatfoot, the feet should be supported with adhesive straps at the outset and simultaneously suitable tonic eliminative drugs should be prescribed. Later, from response to these two measures, and after taking into consideration all circumstances and special conditions of the patients, the strapping may be continued, shoes changed, plates fitted, special exercises prescribed, or plaster casts applied, according to the physiological requirements. These conditions are sometimes due to vascular defects, and the regulation of vascular defects sometimes is simple, although the defects themselves are complicated or unknown. Unnecessary surgery and too much treatment with orthopedic appliances should be avoided by taking into account the severity and duration of abnormal symptoms and by remembering that pronounced anatomic peculiarities are often compatible with continued normal physiological activities. One should explain to patients the limitations and possibilities of comprehensive methods of treatment and of special ones sufficiently for them to understand the necessity of the former for the best results, and one should also demonstrate the inadequacy of any single method of treatment, old or new, in fulfilling the various requirements likely to be met. Common and comparatively trivial foot troubles require nearly as comprehensive understanding for their skillful treatment as serious orthopedic conditions in other parts.

2. The prognosis of Incipient Senile Cataract.—David W. Wells endeavors to show that a much more optimistic prognosis is justifiable in incipient senile cataract than is usually given by medical men who have not devoted special attention to the eye. He has found from the records of private patients over fifty years of age that have come under his observation from 1900 to 1915 that 23 per cent. had some demonstrable capacity of the lens, though in many cases the sight was but little if at all affected. Sufficient time has now elapsed to enable the writer to report on the cases seen between 1900 and 1905, and as nearly as can be estimated not more than one per cent. of the truly incipient cases have matured and not more than 5 per cent. of these have materially advanced. From this it appears that the prognosis of incipient senile cataract untreated is extremely good. Most of the cases that have come to operation have been nearly or quite mature when first seen. With a preliminary iridectomy and a preliminary capsulotomy the immature lens may be safely extracted. The preliminary iridectomy is done three or four weeks before extraction. The preliminary capsulotomy, which is performed if the lens is immature, consists in introducing the knife needle through the cornea and incising the capsule. The object sought is the loosening of the capsule from the cortex by allowing the aqueous to penetrate it. This is done the evening prior to the extraction. Most incipient cataracts never advance enough to need operation; therefore, one should avoid the term "cataract" and give the most hopeful prognosis until it is evident that it is progressive. Then if it does mature operation offers a good prognosis. If the sight of the better eye is insufficient for reading, the immature cataract of the more advanced eye can be removed without waiting for ripening.

3. The Radical Treatment of Peritonsillar Abscess by Tonsillectomy During the Acute Stage of the Disease.—Harry A. Barnes says that for many years he has been operating on peritonsillar abscess by a capsular dissection of the tonsil backward until the abscess cavity is reached, and with very satisfactory results. At the suggestion of Dr. A. Coolidge he has carried the operation a step further and dissected the tonsil out completely. The theoretical dangers that a general anesthetic is not safe on account of the possibility of pulmonary infection from inspired pus and that operation on an acute inflammation of the tonsil opens a fresh field for infection do not exist beyond that which may be present in the dissection of any tonsil. The operation in these cases differs only slightly from the usual procedure by the dissection method. It is essential that the dissection be a clean one and that the muscular walls of the sinus be as little injured as possible. To avoid opening the larger veins it is essential that the field of operation be seen at every step. The writer describes the technique by which he manages to do this. After the first incision in the plica is made, a retractor not unlike the Kinnian retractor for the lacrymal sac, is inserted by an assistant under the free edge, and the pluca and pillar gently pulled outward and forward. At the same time the tenaculum holding the tonsil is pulled inward, so that the line of demarcation between the capsule and the sinus wall is easily discernible at the apex of the resultant V-shaped cleft between the two tissues. The slightest touch of a sharp knife deepens and widens this cleft, which is in this manner extended backward until the abscess cavity is reached. When the pus is completely evacuated the dissection is carried on as before until the tonsil is sufficiently freed to allow of the easy application of the snare. The results of the operation are particularly gratifying, especially to the patient, since symptoms subside with remarkable rapidity.

4. Notes of a Conference on the Medical and Social Aspects of Syphilis of the Nervous System.—Harry C. Solomon and Hilmar O. Koefod present a study consisting of interval cell counts in cases diagnosed as general paresis or cerebrospinal syphilis (assuming that it is not always possible to make the differential diagnosis) in a series of 46 cases. Treatment consisting of mercury, salvarsan intravenously, and potassium iodide was given in 19, the other 27 cases receiving no treatment. The counts were made at varying intervals in the cell chamber of Fuchs-Rosenthal, staining with Unna's polychrome methylene blue in the pipette. Other tests were also performed on these fluids, namely, the Nonne-Apel test for globulin, Mestrezat test for albumin, Lange's gold sol test, and the Wassermann reaction. The authors conclude that one is not justified in drawing any conclusions as to whether the case is cerebrospinal syphilis or general paresis, nor the time the process has been active, nor the severity of it from the cell count. The cell count may vary greatly from month to month, or when the interval is but several days, while at other times it may remain very nearly the same after an interval of months. Cases showing natural remissions may show no reduction in the cell count or other spinal fluid findings. Treated cases having the cell count fall to normal may at the same time become very much worse and develop more marked paralytic symptoms. In general paresis the cell count in no way parallels the other spinal fluid findings. The change in cell count seen in syphilitic disease untreated, is also found in non-syphilitic diseases, as brain tumor. The cell count offers nothing of prognostic importance in syphilis of the nervous system, unless accompanied by improvement of other labora-

changes may occur on the fingers of those engaged in routine work with radioactive substances. These local objective changes consist chiefly of flattening of the characteristic ridges, thickening and scaling of the superficial layers of the skin, and even atrophy and intractable ulceration. The lesions are usually slight compared with the marked subjective symptoms, such as parasthesia, anesthesia of varying degree, tenderness, throbbing, and even pain. The persistence of such effects is noteworthy. Various general systemic symptoms and also blood changes may be produced by exposure to radioactive substances. To avoid such local and general disturbance, special protective and preventive measures have been devised, and those engaged in routine handling of radioactive substances are particularly cautioned.

2. **Physician and Weather Bureau.**—Ford A. Carpenter. (See MEDICAL RECORD, October 2, 1915, page 585.)

3. **Ulnar Nerve Paralysis.**—J. Ramsey Hunt reports three cases and concludes that tardy or late paralysis of the ulnar nerve is a well defined clinical type of chronic interstitial neuritis, consequent on old injuries and deformities about the elbow joint. The interval of time elapsing between the reception of the original joint lesion and the onset of neuritic symptoms may vary from six to thirty-nine years. During this latent period there are no symptoms other than those referable to the deformity and restricted movements of the elbow joint. The joint lesions most commonly associated with this form of neuritis are those resulting from old fractures and dislocations about the elbow joint, and very rarely old arthritis. Especially frequent is the fracture of the external condyle with cubitus valgus and alterations in the configuration of the ulnar groove. The neuritic symptoms are slowly progressive and run an extremely chronic course. They consist of atrophic paralysis limited to the ulnar distribution with corresponding sensory disturbances. The sensory symptoms, both subjective and objective, may be insignificant and in the earlier stages even absent. The diagnosis rests on the presence of an old joint lesion and the neuritic character of the symptoms. In differential diagnosis the progressive spinal atrophies and the hypothenar type of neural atrophy (compression neuritis of the deep palmar branch of the ulnar) will demand consideration. Surgical measures are usually necessary to check the progress of the atrophy and restore function. Among the procedures advocated in the different types of cases are: enlargement and remodeling of the ulnar groove; resection of the thickened portion of the nerve trunk; transposition of the ulnar nerve to the anterior surface of the internal condyle, and supracondyloid cuneiform osteotomy of the humerus to correct the valgus deformity.

4. **Hypertrichosis.**—G. R. McAuliff reports a case of marked hypertrichosis, observed in the gynecological service of Dr. L. E. Frankenthal at the Michael Reese Hospital, which was studied with the intent of determining the connection between abnormal hair development and genital changes. The writer and his colleagues who have been interested in this study believe that it is justifiable to assume that the suprarenal is the gland principally concerned with sexual characteristics, the pineal next, and then the hypophysis, ovary, thymus, and thyroid, in the order named. It seems that one functionally imperfect gland alone is not able to produce marked hypertrichotic changes, but that at the basis of such change there must be some profound and complex disturbance of the antagonistic and synergistic pluriglandular equilibrium.

5. **Intramuscular Injections of Whole Blood in Purpura Hemorrhagica.**—H. W. Emsheimer concludes that the best methods of treating this condition, in addition to the usual measures, are the subcutaneous or intravenous injection of human blood serum, transfusion, and intramuscular injection of whole fresh human blood. The intramuscular injection of whole blood is a simple, harmless, effective procedure in all cases of severe purpura hemorrhagica; it may also have a wide field of usefulness in hemophilia and other blood diseases; in bleeding from various parts of organs of the body; in wasting diseases, and in many infections.

6. **Proteolytic Ferments of the Blood Serum in Tabes Dorsalis and General Paresis.**—Frederick Howard Falls reports a series of cases of tabes dorsalis and general paresis which he has studied by the Abderhalden method. He has incorporated a series of cases of meningitis which may be regarded as control experiments, as they all gave negative or very faint reactions. Another series of pregnancy cases was also used for comparison, the results of which showed that certain of the cases of tabes and general paresis reacted fully as strongly as some of the cases of pregnancy. The writer concludes that the ferment activity of the blood serum is increased above the normal in tabes dorsalis and general paresis, and that this increase is greater in general paresis than in tabes dorsalis.

9. **Acute Typhoid Abdomen.**—Charles M. Remsen calls attention to the fact that it has been fairly well demonstrated that the occurrence of acutely inflamed appendices in typhoid fever is more than a coincidence. In a series of nine cases in which he has operated for suspected perforation, four showed acute appendicitis, and all showed surgical complications. The two factors contributing mainly to acute appendicitis are the inflammatory edema of the ceco-appendiceal opening, with consequent retention of its secretions, together with the associated circulatory and inflammatory complications usually found under such conditions, which may or may not be due to the activity of the Eberth's bacillus, and actual involvement of the appendiceal lymphoid tissue by the typhoid bacilli in a method similar to that seen in Peyer's patches. With the danger signals of peritoneal inflammation appearing, the possibilities must be carefully weighed, for without extreme care in the diagnosis a patient may be consigned to death whose chances of getting well should he be subjected to surgical intervention are 1:2 or 1:3.

10. **Etiology of the Current Epidemic of Respiratory Infections in Chicago.**—George Mathers has made a careful bacteriological examination in 24 cases of respiratory infection during the present epidemic. In 17 instances a hemolytic streptococcus has been found to be the predominating organism. The strains examined culturally presented all the characteristics of the *Streptococcus pyogenes* type. Green-producing streptococci and pneumococci have uniformly been found in these cultures. The *B. influenzae* and *Micrococcus catarrhalis* have not been found in any of these cultures. A striking fact brought out by this study is that the diagnosis of influenza is rarely corroborated by bacteriological findings.

6. Subcutaneous Injection of Distilled Water for Multiple Ulcers. G. Arbour Stephens.

2. Gunshot Wounds of the Alimentary Canal.—Cuthbert Wallace finds that the percentage of abdominal perforating wounds to total wounds varies considerably at different clearing stations. Thus the figures of four casualty clearing stations give a percentage of 1.88, 1.5, 0.75, 0.62 perforating abdominal wounds to the total wounds. The statistics from nine field ambulances and six casualty clearing stations for a period of six months show that the mortality from wounds of this nature is 70 per cent. To this deaths at the base hospitals in France and England must be added. The author discusses the influence of position of the wound and direction of the missile on the probable nature of the internal injury in regions above the transpyloric plane, between the transpyloric and intertubercular planes, and below the intertubercular plane. Wounds in all these regions are of course very serious, but those between the transpyloric and intertubercular planes are very fatal. It is frequently difficult to make sure that a wound is penetrating. As a criterion of visceral penetration no reliance is to be placed on the non-obliteration of liver dullness, neither can rigidity nor the signs of hemorrhage always be depended upon. It can be definitely stated that the old belief in the spontaneous cure of a gut wound is fallacious and dangerous. It was based on insufficient data and has been responsible for loss of life. As to the results of early operation, at present it may be said that many lives have been saved, that all sorts of injuries have been successfully dealt with, and that no one who has practised operative treatment is in doubt as to the wisdom of the procedure. The mortality at the casualty clearing stations has been reduced, and that in spite of cases that formerly died at the field ambulances reaching the casualty stations, and in spite of a more accurate discrimination between penetrating and non-penetrating wounds which would tend to increase the percentage of mortality. In resection, circular enterorrhaphy has given the best results, as it is quicker than lateral anastomosis, and failure of the suture line need not be reckoned among the causes of failure.

4. Renal Retinitis and Epidemic Nephritis.—R. Foster Moore has made an ophthalmological examination of 119 soldiers suffering from epidemic nephritis recently returned from France. He says there is no doubt that the very great majority of these 119 men were suffering from a primary acute nephritis. In five of these men renal retinitis was present or developed while they were under observation. Of the remaining 114 there were seven in whom very small retinal hemorrhages were present. The retinitis which developed did not differ in any essential from the retinitis of chronic nephritis. In each of the men in whom it occurred the general symptoms were severe, and in general, the more severe these symptoms the more extensive were the changes in the retina. The relation between an increased blood pressure and the development of retinitis is brought out by these cases for the average systolic pressure of 70 cases with normal fundi was 143 mm., whereas that of the five cases in which retinitis developed was 180 mm. This does not imply that local vascular disease is the main factor in the development of retinitis; indeed, the changes present for the most part were of the type considered to be an expression of the toxic element in the disease. It seems from this study that strength is lent to the view, that retinitis does not occur in primary acute nephritis, but that, when the acute condition gradually and directly merges into a condition of chronic nephritis, retinitis may coincidentally develop.

In this latter case the signs of retinitis may be seen as early as within seven or nine weeks of the onset of symptoms of the acute disease.

5. Bullet Wound of the Esophagus.—A. W. Nuthall reports this case because of the rarity of this injury, this being the only injury of this kind that he has seen among some 8,000 wounded treated in a casualty station in six months. The reason for this is the probability that injury to the esophagus is overshadowed by the more serious, if not immediately fatal, effects produced by wounds of important structures in its proximity. The patient was received at the clearing station in a condition of grave collapse and urgent dyspnea and died three days later. At autopsy it was found that the bullet had passed between the esophagus and the cervical spine, perforating the posterior wall of the gullet, behind the common carotid artery, wounded the right internal jugular vein on its posterior surface, crossed in front of the cervical nerve trunks, to come to rest on the scapula. The perforation of the esophagus had caused, by leakage and infection, a prevertebral abscess and below it a larger prevertebral abscess had burst through the dome of the pleura on its inner aspect into the pleural cavity.

7. Method for Quick Detection of *S. pallida*. W. H. S. Stalkart.
8. Fallopian Tube and Ovary in Infantile Hernia. H. H. Taylor.

1. A Classification of Meningococci.—Arthur W. M. Ellis shows that by means of a specific immune reaction two types of organism causing cerebrospinal fever can be demonstrated, and that of 46 organisms studied all belonged to one or other of these types. Both types are widely distributed, having been found in each of six epidemic foci and they may occur with equal frequency. Both types have been found in the nasopharynx of healthy carriers. These two types have been designated Type I and Type II. In so far as evidence is available Type I has been more frequently the cause of the disease in recent epidemics than has Type II. In view of the wide distribution of the two types, both must, however, be held equally responsible as causative agents of cerebrospinal fever. The organism which the writer describes as Type II is probably identical with the parameningococcus of Dopter. It is suggested that in the treatment of cerebrospinal fever better results might be obtained and more exact knowledge of the adequacy of serum treatment gained, if monovalent horse serum of appropriate type, and therefore known to be active against the infecting organism, were employed in place of the polyvalent serums at present in use.

2. Grouping of the Strains of Meningococcus.—Joseph A. Arkwright writes an account of his observations on strains of meningococcus isolated from the cerebrospinal fluid or meninges of cases of meningitis. He found that 30 out of 32 strains of meningococci tested agglutinated with a polyvalent rabbit serum prepared with six strains isolated in the same epidemic. Thirty strains isolated during the present epidemic fall into two main groups according to agglutination tests. Five other strains presented difficulties in their classification. The two main groups correspond to Dopter's classi-

cation into meningococcic and parameningococcic strains. The numbers falling into the two groups were 18 and 12 respectively. There is some evidence that two of the five unclassified strains were intermediate in character between the two main groups. Neither group was found more frequently among cases from one district than from another. Rapidly fatal cases of meningitis occurred with infection with either type of meningococcus.

3. Effects of Exposure to Wet Cold.—S. Delépine describes experiments made to determine the effect of exposure of the extremities of a healthy elderly adult to external media colder than the skin and finds the results widely different according to circumstances. The lowering of temperature caused by exposure to cold dry air was slight and not progressive. The loss of heat was obviously compensated by the heat yielded by the tissues and the circulating blood. The lowering of the temperature caused by immersion in a limited amount of water was rapid and considerable but not permanent. When the bulk of the water did not exceed twice that of the part immersed, enough heat was yielded by the tissues and circulating blood to warm the water to a temperature which was not detrimental to the part. The lowering of the temperature caused by immersion in a large amount of water at a temperature of 25° to 30° C. below that of the skin, or water in limited or unlimited quantity containing ice, was very rapid, considerable, and progressive. A pathological state, local frigoris, was invariably the result. This state was characterized by contraction of the small arteries, more or less complete arrest of the flow of blood, various degrees of anemia, and irritation of terminal nerves followed by nervous and muscular paralysis. Motion of the external fluid prevented the formation of a comparatively warm layer of fluid near the surface of the skin and accelerated the loss of heat. A thin layer of moderately dry air between the skin and a cold external medium was sufficient to reduce the loss of heat to such an extent that the circulating blood compensated for the loss after the temperature of the skin had been reduced a few degrees. A very thin waterproof covering used in combination with a woolen covering was found sufficient to secure an efficient air covering for the skin. The presence of some moisture under it reduced the efficiency of the waterproof covering, but did not render it useless. These facts suggested to the writer the possibility of devising suitable protection against wet cold which would be adapted to the needs of the soldier. He describes the waterproof bag which he has succeeded in making and shows that with the same material it is possible to secure a sufficient amount of protection against the effects of wet cold without discarding the boots at present supplied to the army.

4. The Carrier Problem at Home in Time of War.—Edward C. Hort describes the Addington Park War Hospital, the routine employed there in the search for carriers of the enteric group of organisms, and the technique employed in making fecal and urinary examinations, and serological tests. He says the experiences of the moment do not permit of definite statements.

Berliner klinische Wochenschrift.

November 1, 1915.

Diseases of Fishes.—Schiemenz objects to the saying "as sound as a fish in the water," for these creatures have a very extensive morbidity and mortality. The percentage of eggs which become sound adult individuals must be infinitesimally small. The supposed health of fishes arises from the fact that under ordinary conditions sick specimens are seldom encountered. These sink to the bottom, are washed up on the shores, and in

any case are quickly devoured by predatory fish and fish-eating birds. To begin with the ova, many never hatch, aside from the great number which never become fertilized. Many kinds of fish, notably the eels, consume large quantities of spawn. The latter is also attacked by bacteria and protozoa, as are also the young fry. These two orders, along with young crustaceans and annelides, also cause many diseases which do not destroy outright. The bacteria form the worst enemy, some of them first attacking the digestive organs, and secondarily the muscles and skin. Other parasites attack the fish from without, and some literally eat them alive. In some cases these parasites convey trypanosomes into the blood. The fish often serves as a host for intestinal worms, which are not directly a peril, but which appropriate nourishment. Some of the predatory fishes are distended with tapeworms. Sporozoa attack the digestive organs, viscera, and skeleton, and form collections under the skin which rupture outwardly and thus spread the infection. Malformations are extremely common and varied in fishes, and neoplasms have in recent years been the object of much study.

Tuberculosis and Climate.—Schlesinger cites many interesting historical data on this subject. The fathers of medicine were accomplished climatotherapeutists. The elder Pliny was aware of the favorable influence of pine forests on tuberculosis. Galen sent his consumptives to Mount Angri, near Naples, while Avicenna recommended Crete. In modern times Laennec recommended the sea air and Hufeland and Schönlein mountain air. It was noted by many that mountain dwellers enjoyed an immunity to consumption. But it is only too evident to the physician with insight that other factors must divide the credit for cures with mere altitude. There is the removal from the often depressing influences of the home circle, the regulated life, including suitable diet and clothing, the autosuggestion (naturally the author assumes that the patient has sanatorium accommodations). Moreover, there must be an acclimatization, which is not accomplished without some strain on the important body functions, depending, of course, on the altitude. Climate is a comprehensive term, which includes air pressure, prevalent winds, humidity, heat, light, precipitation, amount of ozone and other gases in the air, amount of dust and dampness in soil, etc., etc. Some of these conditions vary directly or inversely with others. As we rise progressively above sea level we get more and more precipitation, as well as more and more light, the temperature likewise sinking and the pressure rising. The motion of the air depends in the highest degree on the barometric pressure. Change in climate may involve a simple change in one particular regard, without abandoning the immediate neighborhood—as from the windward to the leeward side of a mountain slope—or a more radical change in which most of the factors are involved. It is in this direction that much work remains to be done. In any climatic change, despite diversity of factors, one of the latter must be dominant—as high, dry, etc. Immunity of natives must always be considered, and here we encounter most stubborn facts. For example, in the so-called Eastern Polar Regions tuberculosis is practically unknown, while in the corresponding Western area it is common. Such inexplicable data, along with the really myriad factors (some unknown) which go to make up a climate make the author somewhat skeptical as to the prospect of a scientific climatology.

Berliner klinische Wochenschrift.

Difficulties in the Diagnosis of Cancer of the Gall Bladder.—Kehr has now treated forty-nine cases of this

lesion. At the outset, various clinical pictures may be presented. The course may be very mild, suggesting a simple gastric catarrh, or violent, simulating an acute empyema of the gall bladder. This diversity depends entirely on the location, the presence or absence of stones, etc. A small nodule of cancer in the fundus may cause no more disturbance than a cholesterol stone. When the serosa is reached the symptoms may still be mild; while if the cancer spread into the liver bed, it may give rise to no symptoms whatever. The picture changes entirely when the growth begins at the neck of the bladder. The cystic duct is at once closed. If stones are present an acute cholecystitis develops from infection. The diagnosis can be nothing beyond cholecystitis or cholangitis. A cholecystotomy cannot necessarily lead to a correct diagnosis. The author enumerates five cases of missed diagnosis in one of which even an inoperable cancer was overlooked. This was due partly to the fresh, blooming look of the subjects, one of whom was but 37 years of age. But these five failures were by no means the only ones, being given only as illustrations. Is there no way in which we can arrive at a suspicion of malignancy? The personal history is but seldom of use. How can a simple picture of cholecystitis with jaundice suggest a cancer in one case and not in another? Absence of typical biliary colic might have a very restricted value. Cancer pain is absent or at least obscured by the pains of cholecystitis or empyema. The author derived no benefit from seroreactions, but by all means advises their employment. Cholecystotomy is of little value *in vivo*; a simple ulceration can simulate a cancer. Concrements are present in the great majority of cancerous gall bladders, either as a coincidence or as a result of cancerous obstructions. In a small percentage of cases the irritation of the stone has determined the appearance of cancer. The only advice the author can give is to remove all gall bladders with symptoms of severe cholecystitis or empyema, but the indication for this course is already present. If severe symptoms are absent we can only know that an ectomy will now aid them to reveal an operable cancer; and if we have any suspicion of the latter we must extirpate the organ. For the rest the patient may decide if told that a sure prognosis requires a radical operation. Kehr also discusses difficulties of diagnosis in advanced cases of cancer of this viscus. We are supposed to have the symptom-complex of a hard tumor, jaundice and ascites with cachexia. Yet all these symptoms may occur without cancer. The hard, uneven mass felt in the gall bladder site may be only a calcification. Not a few lives have thus been lost because of the diagnosis of inoperable cancer. Masses of stones in the common duct have similarly been mistaken for cancer, especially by reason of the cachexia which finally overtakes victims of chronic cholangitis and pancreatitis. Ascites is by no means significant of cancer in these cases, as it may be due to extension of cholangitis to the liver and branches of the portal vein. Cancer pain is indistinguishable from cholangitis pain although true colic does not occur as a result of the former. Trial laparotomy cannot make the diagnosis with certainty. Whether or not because of these inherent difficulties of diagnosis the author has to his credit but one permanent cure (out of 49 operations) of gall bladder cancer.

November 15, 1915

Treatment of Renal Diseases.—Hirschfeld obtained far-reaching benefit in certain cases of contracting kidneys by a diet very low in protein—only 30 grams of absorbable albumin, to which he added 5 grains of

sodium chloride. The diet was made up chiefly of vegetables, potatoes, rice, cream, sugar and fruit in large quantities. Under this regimen the polyuria sinks to $\frac{1}{4}$ liter in 24 hours and is usually alkaline or amphoteric. If still acid, alkalies should be administered as an alkaline reaction is a desideratum. As a rule a fall of blood pressure is noted after two weeks of this diet. Two hours daily of walking is also of the greatest benefit, because it shows up the nitrogen excretion and thereby spares the kidneys and reduces the albumin in the urine if this is present. The author evidently believes strongly in the anginal origin of many cases of nephritis. The use of sodium chloride in these cases appeared to be largely intended to determine the degree of intolerance to the substance as the patients are elsewhere stated to be on a salt poor diet, and the attempts to keep the urine alkaline seem to be with the view of warding off an acidosis. The article will be continued and doubtless somewhat random statements will be properly summed up.

Positive Wassermann Reaction in Pemphigus Vulgaris.—Nathan refers to a recent communication by Hesse, from which it appears that in both pemphigus vulgaris and dermatitis herpetiformis a positive Wassermann reaction is often obtainable. Such finds do not straightforwardly prove the syphilitic nature of either of these dermatoses, for syphilitics are predisposed to various eruptions, to say nothing of pure coincidence. The eruptions in question have never been associated clinically with syphilis, and moreover the reaction may be weakly positive in certain dermatoses which can hardly be confused with lues. Nathan selected twelve cases of pemphigus in which no evidence of syphilis was obtainable and tested them with a variety of sera. In not one test was a positive result obtained. Two of the cases tested were examples of pemphigus vegetans, an affection which may closely simulate syphilis at times. Cronquist of Denmark once claimed as a result of a positive Wassermann that a case of alleged pemphigus vegetans was syphilitic, but he was antagonized in this view by his colleagues. Doubtless Hesse used a too refined and sensitive extract, and his modified drop method may have been open to the same objections as those of others who have obtained a paradoxical reaction in the non-syphilitics. The greatest serologists have in fact advised the utmost caution in using the drop method.

Increased Consumption of Alcoholic Beverages in the United States.—The average annual consumption of distilled spirits, wines, and malt liquors in the United States from 1850 to 1914 is stated in gallons as follows, the figures being copied from the recently published "Statistical Abstract of the United States" issued by the Department of Commerce at Washington: 1850, 4.08; 1860, 6.43; 1870, 7.70; 1871-89, 8.79; 1881-90, 13.21; 1891-95, 17.12; 1896, 17.12; 1897, 16.50; 1898, 17.37; 1899, 16.82; 1900, 17.76; 1901, 17.65; 1902, 19.14; 1903, 19.57; 1904, 19.87; 1905, 19.85; 1906, 21.55; 1907, 22.79; 1908, 22.22; 1909, 21.96; 1910, 22.19; 1911, 22.79; 1912, 21.98; 1913, 22.68; 1914, 22.50.

Summer Eruption.—G. F. Stebbing reports a case of this condition in a girl, aged 14 years, who developed, five years ago, a rash on the hands and face, which has persisted ever since, with remarkable seasonable variations. Every winter the rash practically disappears, and every spring it comes back again. It is rendered worse by exposure to the sun; vesication and pustulation occur, and in some places there have been large weeping sores, which take several days to clear up. The red blood cells were about 6 millions, and of the white cells 50 per cent. were small mononuclears.—*Proceedings of the Royal Society of Medicine.*

Book Reviews.

TEXT-BOOK OF FORENSIC MEDICINE AND TOXICOLOGY. By R. J. M. BUCHANAN, M.D., F.R.C.P. Lond., etc. Professor in Forensic Medicine and Toxicology, University of Liverpool; Honorary Physician, Royal Infirmary, Liverpool, etc., etc. Eighth Edition. Revised and Enlarged. Pp. 417. Price, \$3.25, net. New York: William Wood & Company, 1915.

THAT a work in its eighth English edition should be unknown in the United States is due to the fact that it is a lineal successor of Husband's Forensic Medicine, which has gone through seven editions. In the present edition it appears for the first time in two volumes. The first of these, PUBLIC HYGIENE, with Professor Hope's name on the title page, has already appeared. The present volume, evidently entirely from the pen of Professor Buchanan, is devoted to forensic medicine and toxicology, as the title states. Works on these subjects have to be conservative and must at the same time seek to value correctly all that is new and novel; and considering the very narrow limits allowed the author, the labor of condensation leaves little to be desired. Perhaps a weak point is the extreme conservatism used in classifying and describing the forms of insanity, which would hardly be intelligible to our students of to-day. But this subject makes up a relatively insignificant portion of the book. The latter is well illustrated, chiefly with photomicrographs.

DISEASES OF THE NOSE AND THROAT. By ALGERNON COOLIDGE, A.B., M.D., Professor of Laryngology in the Harvard Medical School. Laryngologist in the Massachusetts General Hospital. Illustrated. Price, \$1.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

THIS work by Dr. Coolidge covers fully the subject of the nose and throat mainly from the clinical point of view. In fact the book was written with the object of guiding the student or practitioner of medicine in his clinical work, by giving him a ready reference to the important details of examination, diagnosis and treatment of the upper respiratory tract. It is conceived upon the plan of presenting the different subjects in their proper perspective which is all that a small manual is able to accomplish. Dr. Coolidge has succeeded well in his object, and there is no doubt that the book will serve the purpose for which it was intended excellently.

THE BOOK OF THE FLY. A Nature Study of the House Fly and its Kin, the Fly Plague and a Cure. By G. HURLSTONE HARDY, with an introduction by HALFORD ROSE. New York: Rebman Company, 1915.

THE menace of the house fly has been recognized but recently. However, now it is fairly well understood even by the general public that the house fly is a very fertile source of danger. In the book written by Major Hardy the house fly is discussed from the naturalist's point of view as well as from the standpoint of disseminator of disease. The result is a work which is at the same time interesting and instructive, useful and practical.

BACTERIOLOGICAL METHODS in Food and Drug Laboratories with an Introduction to Micro-Analytical Methods. By ALBERT SCHNEIDER, M.D., Ph.D., Professor of Pharmacognosy and Bacteriology in the College of Pharmacy of the University of California, San Francisco. Price, \$2.50. Philadelphia: P. Blakiston's Son & Co., 1915.

"THIS volume is primarily intended as a guide to students who are interested in the bacteriological examination of foods and drugs." It is a compact and complete guide giving methods in detail and furnished with many illustrations which aid materially, especially in the recognition of microscopic findings. The appearance of such a book is a welcome index of the importance which has been attained by the bacteriologist in the standardization of our supplies of food and drugs. Already the standard of excellence for many of our foods involves a bacterial limit and in some drug preparations the absence of bacteria is highly essential and it is reasonable to suppose that in the course of time these standards will be made to include many other products. Such a work will therefore prove useful in the hands of many laboratory workers. One very complete section is devoted to the standardization of disinfectants. The few errors noted may be blamed on oversight, as where on page 198 the statement is

made that pus cocci remain active in 10 per cent cocaine and five lines below that solutions of cocaine (1-10) "are usually quite free from bacteria." The susceptibility to eggs in some people is blamed on the presence of some toxin or to "idiosyncrasy." It certainly would be more accurate to classify it as anaphylactic. The book can be recommended to those interested.

HOW TO LIVE. Rules for Healthful Living Based on Modern Science. Authorized by and prepared in collaboration with the Hygiene Reference Board of the Life Extension Institute, Inc., by IRVING FISHER, Chairman, Professor of Political Economy, Yale University, and EUGENE LYMAN FISK, M.D., Director of Hygiene of the Institute. Price, \$1.00 net. New York and London: Funk & Wagnalls Company, 1915.

THE purpose of the book is well presented in the preface. It is to promote the aims of the Life Extension Institute . . . (1) to provide the individual and the physician with the latest and best conclusions in individual hygiene; (2) to ascertain the exact and special needs of the individual through periodic health examinations; (3) to induce all persons who are found to be in need of medical attention to visit their physicians. . . . The subject matter of hygiene is treated in its relation to (1) the preservation of health; (2) the improvement in the physical condition of the individual, and (3) the increase of his vitality."

It is a book to be read—and reread at intervals. The person who is growing stout with increasing years, the person who fears a draft, the person to whom good food is an exaggerated pleasure, will all find reasons for readjusting to better standards of living. Statistics carefully used are strong arguments and such life insurance statistics as are used in this book make an impressive appeal.

The book is one of facts—the need of activity, the need of more vegetable food and less meat than is commonly used in America, the evil effects of tobacco and of alcohol are presented with equal honesty and poise. By following the directions in "How to Live" each of us might increase our efficiency and our length of life.

THE NOSE, THROAT, AND EAR; THEIR FUNCTIONS AND DISEASES. A Treatise upon the Breath-road, Food-road and Accessory Organs. By BEN CLARK GILE, Instructor in Otology in the University of Pennsylvania, and formerly Assistant in the Throat and Nose Dispensary of the University Hospital, etc. With 131 illustrations, eight of which are printed in colors; pp. 456. Price, \$2.75. Philadelphia: P. Blakiston's Son & Co., 1915.

THIS book may be termed a "good value" and will undoubtedly have an excellent sale among students of medicine. But why should any writer deem it commendable to substitute for respiratory tract, *breath-road*, for esophagus *food-road*, and for foreign bodies, *extranea*? This reversible pedantry may advertise the work by making it a theme of discussion but will affect unfavorably certain prospective buyers. The term *armamenta* for the physician's equipment is also freakish.

THE CLINICS OF JOHN B. MURPHY, M.D., AT MERCY HOSPITAL, CHICAGO. Vol. IV, No. III, June, 1915. Octavo of 196 pages with 90 illustrations. Published bi-monthly. Price, per year, paper, \$8.00; cloth, \$12.00. Philadelphia and London: W. B. Saunders Company, 1915.

THE value which the reviewer accredits to individual numbers of the clinics doubtless depends in no small degree upon his judgment of the relative values of the subjects discussed in increasing the general practitioner's efficiency. While the description of Murphy's technique for arthroplasty in cases of ankylosis of the jaw and the introduction of a series of excellent plates, showing the various steps in the procedure, make a very interesting and instructive chapter for the skilled operator, a section on the diagnosis of injuries of the carpus, and particularly of fractures of the scaphoid, is of infinitely more value to the practitioner for whose instruction the Clinics are primarily intended. We are glad to see that in this issue Murphy has devoted the section on diagnosis to these problems; and we commend at least this portion of the book to all readers. The comparative rarity of simple sprains of the wrist and the relative frequency of fractures of the carpal scaphoid can hardly be appreciated by one not associated with a large and active surgical clinic.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held November 22, 1915.

THE PRESIDENT, DR. HOWARD LILIENTHAL, IN THE CHAIR.

Election of Officers.—The following officers were elected: *President*, Dr. Frederic E. Sondern; *First Vice-President*, Dr. J. Bentley Squier; *Second Vice-President*, Dr. Charles H. Peck; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. Daniel S. Dougherty; *Treasurer*, Dr. Charles H. Richardson; *Censors* (to serve two years), Drs. Howard C. Taylor, Willy Meyer, and Floyd M. Crandall.

The Diagnosis and Treatment of the Post-Operative Complications of Appendicitis.—Dr. JOSEPH WIENER read this paper, in which he said that as the post-operative complications of appendicitis were so many and varied he would consider only some of the most common ones and some of those less well known without attempting to cover the entire field. (1) **Peritonitis.** Dr. Gerster writing in 1910 reported on 3144 cases of appendicitis operated on in Mt. Sinai Hospital from 1899 to 1909, 461 of which had some free peritonitis. Since that time the number of cases of peritonitis in proportion to those of appendicitis had been steadily declining. This was due to earlier diagnosis, earlier consent to operation, to prophylactic treatment, the early and continued use of the Fowler position, the avoidance of cathartics and opiates before operation, and the use of salines per rectum post-operative. (2) **Intestinal Obstruction.** Cases of intestinal obstruction were much less frequent than formerly, but unfortunately they still occurred and one-third of them ended fatally. Among the measures that tended to prevent this complication were the introduction of a minimal amount of gauze to wall off the intestines, small incisions, rapid work, little or no drainage, except in abscess cases, frequent stomach washings, rectal irrigations and enemata, eserine and pituitrin subcutaneously, and nothing by mouth. In severe cases it might be necessary to open the abdomen and puncture the gut in several places. This was at times a life-saving procedure. (3) **Fecal Fistula.** This was a fairly common complication, being present in about 2.25 per cent. of 4400 cases. More than 80 per cent. of the fistulae healed spontaneously; about 15 per cent. required secondary suturing and less than 5 per cent. required intestinal resection. The internal fistula in which the abscess had opened into the bladder or intestine usually required no treatment. In all persistent cases of fistula one should make a careful search for a foreign body, sponge, gauze, or drainage tube. If the fistula was high up in the intestine there was danger of starvation. In one such case the writer said it had occurred to him that he could collect the partly digested food as it left the proximal loop at the site of perforation of the intestine and inject this into the distal loop. There had been an extensive necrosis of the abdominal wall and he had been able to verify that there were two fistulous openings in the bowel, or rather that a large piece of the anterior wall of the gut had sloughed away. He passed a long rubber tube into each of these two openings and connected the end of each tube with a bottle. The patient was fed freely and a few hours after each feeding large quantities of chylous fluid flowed into bottle No. I. This fluid was slowly injected into tube No. II, and the tube was clamped off for an hour or longer. There was very little leakage from either tube and the patient's general condition immediately improved. By the end of a month she was able to survive a resection of the intestine at the site of the fistula and made a complete recovery. (4) **Pelvic Complications.** These might be divided into ordinary secondary pelvic abscesses and into tubo-ovarian and broad ligament infections. A mass could almost always be felt by rectal or vaginal examination and the treatment was incision through the rectum or vagina. (5) **Thrombosis.** This was one of the most important complications of appendicitis and in its broadest interpretations it would include iliac, femoral, mesenteric, and portal phlebitis with all the complicating lesions caused by emboli, empyema, subphrenic and liver abscesses, gangrene of the intestine, and pyemic abscesses in any part of the body.

With any inflammation of the appendix the veins in its mesentery might become inflamed and lead to thrombosis. This danger from thrombosis did not cease with the subsidence of an attack of appendicitis; neither did it cease with the removal of the appendix. Thrombosis might follow appendicitis by the direct extension of a thrombus from the deep epigastric to the external iliac and femoral veins. (6) **Pneumonia.** This complication was reported as having occurred 45 times in 4500 cases, with a mortality of 33 per cent. The lesion was almost always a bronchopneumonia. Here prophylaxis was of great importance; it included short anesthesia, raising the head and shoulders soon after the operation, frequent changes of position and encouraging the patient to take a number of deep breaths every hour. (7) **Empyema.** This affection was either hematogenous, in which case either side might be involved, or it was often due to direct extension from the subphrenic space and then it was always right-sided. According to some writers the infection was also carried directly by the lymph channels starting from a retrocecal abscess. From this focus there might be an uninterrupted continuation of the lesion up to the subphrenic space. (8) **Pyelophlebitis and Liver Abscess.** At first sight it might be assumed that only grave lesions in the appendix gave rise to hepatic infections. Such, however, was not the case. If one bore in mind Sonnenburg's dictum that every patient that had had an attack of appendicitis was a possible thrombus carrier, one could readily see how, even after an operation was done in the interval stage, emboli might be dislodged from the veins around the appendix and be carried to the portal vein and thus infect the liver. This was by far the commonest method of infection. In some cases the infection took place through the lymphatics and in others through the arteries as part of a systematic infection, and also by direct extension of the suppurative process from the appendix through the retroperitoneal tissue, as Korte had pointed out. Judging from the cases reported, these last two methods were of rare occurrence. But all cases of liver infection did not go on to the formation of a serious lesion and spontaneous recovery in not a few mild cases did occur. The cardinal symptoms in all cases were fever, enlargement of the liver, pain, and emaciation. In some instances one found tenderness and rigidity in the right hypochondrium. Most cases had some icterus. Diarrhea was often present and added to the emaciation. In some cases one could hear a friction nib over the dome of the liver. The diagnosis might be obscured by a complicating pleurisy, empyema, or subphrenic abscess. In many cases the diagnosis could not be made until the aspirating needle found the pus. The prognosis was grave in all cases that went on to the formation of an abscess. The treatment consisted of free incision either by the transpleural route, or the abdomen should be opened and the liver explored and incised from below. (9) **Subphrenic Abscess.** Infections of the subphrenic space were the most fatal of all the complications of appendicitis. The mortality was over 50 per cent. and with some authors it was as high as 80 per cent. In some cases that gave the cardinal symptoms of subphrenic abscess the infection cleared up without operative interference. In two-thirds of Sonnenburg's cases of subphrenic abscess there was a complicating right sided pyothorax. Children were very rarely affected. There was an analogy in these infections to those of the liver, due to the fact that the channels of infection were the same in both instances. The characteristic symptoms usually began from the eighth to the thirtieth day after the operation, though in some cases several months had elapsed. In many cases a diagnosis could only be made by aspiration, and it was surprising how even a large collection of pus in this location would not be found even after many repeated aspirations with a large needle. In some cases the positive diagnosis could be made from a good radiograph. The aspiration was usually done in the operation room and preparations were made to cut down on the needle if pus were found. A large aspirating needle was passed through the diaphragm and as soon as pus was found a grooved director was introduced alongside the needle. Then a narrow dressing forceps widened the opening still further until the examining finger could be passed through the diaphragm into the abscess cavity. All the pockets were broken up so that there was but a single cavity to drain. The liver was palpated to see if there was any abscess which had

perforated into the subphrenic space. In some cases counter incision was needed to secure adequate drainage.

Dr. CHARLES L. GIBSON said that the theories advanced regarding the causation of pulmonary embolism were almost endless and never had there been found a true explanation as to why they should meet with it so often after operations for appendicitis. He spoke of the analogy between thrombosis occurring in the abdominal veins and the work they did in the axilla and neck, cleaning out the lymphatic nodes there with a great deal of trauma, and yet seldom if ever were seen instances in which pulmonary embolism occurred as a sequel. There were two things in particular which he thought very important for them to consider: They should disregard the popular theory that a great many cases of embolism might be referred to prolonged inactivity and rest in bed. The majority of these cases, to his surprise, came on within the first forty-eight hours. Again, the great majority of people had this sequela when they were in middle life. Dr. Gibson said he would like to see a systematic study of a long series of cases, 10,000 or more, in which the Wassermann test was employed; he believed that he would not be surprised to find that in these cases of pulmonary embolism there would often appear a positive reaction. Was the intestinal obstruction an immediate or remote complication in these cases? Was there a true mechanical obstruction? Was there a paresis of the bowel present, active and progressive, when the obstruction occurred within the first forty-eight hours, or three or four days? Dr. Wiener had mentioned a remedy which was absolutely in his opinion a life-saver—pituitrin. With this remedial agent the use of morphine became a humane treatment in the cases calling for it when, without the use of it, morphine would indeed be a dangerous drug. The combination of these two drugs gave great comfort to the patients. In many of the cases of obstruction occurring soon after the operation for appendicitis the reason was difficult of explanation. If it occurred immediately after the operation it would be the result, for the most part, of a paresis. He asked why mechanical obstruction was so hard to diagnose. He believed that in a great many cases a mild mechanical obstruction was due to an agglutination which pituitrin would help to overcome. In diagnosing incomplete obstruction of the bowel he favored giving powdered charcoal by the mouth; when other signs failed him, the use of charcoal gave him great aid in deciding whether to operate or not. This was not of value, of course, in the acute form. With regard to drainage, Dr. Wiener said he did little or none at all; however, if one was called upon to drain, one should drain efficiently. He did not believe in the use of the cigarette drain in these cases; it simply acted as a stopper and defeated the desired end. When very free drainage was necessary as in large uterocoeal abscess, a Mikulicz tampon, made with perforated dental rubber dam was most efficient and prevented the adhesion of the intraabdominal contents to the drain.

Dr. ALEXIS V. MOSCHCOWITZ said that broadly speaking the subject of appendicitis was a most encouraging one and showed what a united profession could do if it only persistently hammered at a certain definite problem. Within a space of a few years it had reduced enormously the mortality of appendicitis, and as was to be expected had also reduced the frequency of its complications. It gave a hope that something would also be accomplished with that other dread disease, cancer. Dr. Moschcowitz said that he had noted in the paper just read that few points contained therein did not coincide with his, and he briefly referred to these as follows: (1) He had discarded the administration of salt solution per rectum. Most patients complained after operation bitterly of thirst and he saw no reason for increasing their thirst by the needless addition of two teaspoonfuls of salt to every quart of water. He obtained just as good results by administering plain water. (2) He had not derived as great a benefit as Dr. Wiener had from the use of Cargile membrane in preventing adhesions. That desideratum of surgery, the prevention of peritoneal adhesions, still remained at the stage of a desideratum. (3) He knew he was treading on thin ice, but candor compelled him to state that personally he was opposed to the promiscuous, so-called prophylactic extirpation of the appendix, in the course of operations undertaken for other lesions. He based his conclusions upon the fact that he had seen

much harm, and even death following this apparently trivial addition. (4) He confessed that up to the present he was not aware that subphrenic abscess was so fatal a complication in the hands of others; it certainly did not coincide with his experience. He was always under the impression that if the diagnosis was made sufficiently early, the prognosis of subphrenic abscess was not bad. (5) That the prognosis in any given case of appendicitis was always in doubt was amply proven by a case now under his care at the Har Moriah Hospital. He said he would not burden them with the detailed history, but in short it was that of a young man upon whom he had operated for an acute gangrenous appendicitis with localized abscess seventeen days ago. For one week the course was absolutely uneventful. On the eighth day he developed pulmonary symptoms and the physical examination led him to make the diagnosis of a septic infarct of the lower lobe of the right lung. This was later verified by the employment of the x-ray. He especially called attention to an interesting temperature chart since that time. Frequent chills with temperatures of 105° F. and over marked the second week. The patient was doing well at present. He did not wish to make any prognostication.

Dr. J. WIENER acknowledged that the use of pituitrin was of the greatest value and he agreed with what Dr. Gibson had stated regarding the use of this agent, which permitted the greater use of morphine in those cases in which it was called for. Since the introduction of pituitrin he had been able to use morphine in abdominal cases more liberally than ever before and repeated the doses whenever necessary. They now had none of those alarming symptoms they formerly encountered when morphine was used alone in abdominal work. In diagnosing a true fecal fistula the use of methylene blue was of great aid; he was in the habit of giving a capsule of methylene blue and noting whether or not the color appeared in the stools. He agreed with all that Dr. Moschowitz had stated. They used salt water in the rectum because "their fathers used it." He always used water in the form of a stimulating enema. The value of the Cargile membrane was very great in his hands and he said he would continue to use it until he was given something better. He emphasized the fact that better results were obtained when the membrane was chromicized; when non-chromicized the membrane disappeared too quickly. The mortality from subphrenic abscess was a great deal less than what had been mentioned. The sooner the diagnosis, the lower the mortality. Great help had been given them by the use of the x-ray; now they could, by its aid, make a positive diagnosis of subphrenic abscess.

Clinical Varieties and Therapy of Precordial Pains Due to Organic Cardiovascular Disease.—Dr. SELIAN NEUHOF presented this communication, in which he stated that the frequent and indiscriminate use of such terms as false angina pectoris, angina sine dolore, angina vasomotoria, etc., with no clear sense of their etiology or pathology had added to the difficulties of comprehending the fundamental cause of precordial pains due to cardiovascular disease. This confusion and the fact that precordial pains of similar distribution and character might be caused by both intra- and extra-cardiac disease had stimulated the reader to a careful study of those patients in whom these pains, from whatever cause, constituted a prominent symptom. In every case a careful history was obtained and, besides the routine, the examination often included phthalein and sodium chloride excretion tests, and electrocardiographic and orthodiascopic tracings. The type character, intensity, and distribution of the pain, the time of its appearance, and its correlation with exercise, with digestion or other disturbances, and the presence or absence of Head's zones were noted. After a study of all the data, an attempt was made to discover the probable fundamental etiological lesion in the cardiovascular system or in a distant organ and to gauge the extent and severity of the pathological damage to be therapeutically attacked. In this way, besides obtaining a rational view of the entire subject one could fairly definitely pick out and group patients in whom therapy would be of no avail, as well as those in whom it offered good chances for relief and even symptomatic cure. Some of the commoner and more important varieties of precordial pains due to organic cardiovascular disease might be discussed under the following headings: (1) Hypertensive Cardiovascular Disease with Myocardial Insufficiency. In this group of cases the usual cardiac

changes were ventricular hypertrophy, usually left, but sometimes right also; a patchy fibrous myocarditis; thickened aortal and mitral cusps; lime deposits on the first portion of the aorta and atheroma and thickening of both coronaries. These cases were characterized by a systolic blood pressure of about 190 mm.; rough systolic first and sharply accentuated second sound at the right base; heaving apical impulse; urine with or without albumin or casts; varying grades of edema and visceral congestion; dyspnea usually upon exertion. The pains were commonly dull, most marked in the precordium and radiated to the neck and arms. The long list of remedies that had been used in this condition was sufficient to prove their inadequacy. As to the cause of the pain it seemed that the underlying factor was nutritional cardiac disturbance from inadequate coronary circulation. The author in these cases had placed his main reliance on digitalis, preferably the tincture, given in 15 mm. doses three times a day and should not be stopped when pain and other symptoms disappeared, but should be continued for an indefinite period. Mental excitement and stress should be avoided. For the elimination of the edema, theobromin sodium salicylate in one-gram doses three times daily on alternate days in water or in wafers might be recommended. The Carrel diet was an excellent aid. In cases in which a luetic condition was proved or suspected the iodides were useful, otherwise the reader had found them of no value in the relief of the pain. (2) Hypertension and Myocardial Insufficiency with Unstable Vasomotor Mechanism. This was a smaller group of cases with the highest systolic blood pressure around 180 and with marked diurnal variations, precordial pains following exercise. Emphysema and myocarditis were the main pathological entities. Experimental subcutaneous injections of nitroglycerin in doses of one-fiftieth of a grain three times a day had a marked temporary effect upon the blood pressure and usually upon the symptoms. Nitroglycerin or other vasodilators given at the onset of pain were likely to be followed by great relief. Digitalis was not as beneficial as in Group 1. (3) Uremic Group. This group was characterized by headache, nausea, vomiting, varying grades of anemia, paroxysmal dyspnea, precordial distress, high systolic and diastolic pressure, nocturnal polyuria, and changes in the retina. The precordial pains were not relieved by nitroglycerin, digitalis, or diuretin. The pains were apparently caused by retained excrementitious products flowing in the general circulation. Dietetic measures, especially low protein and high carbohydrates, were of most value. (4) Acute Rheumatic Endocarditis and Rheumatic Endocarditic Exacerbations. These cases usually occurred in young persons with mild tachycardia, no dyspnea or decompensation, and with marked auscultatory evidence of valvular disease, usually mitral stenosis. The main complaint was that of sticking pains localized in the heart itself. There were usually no Head's zones. The rapid heart action and the precordial pain seemed to be due to the effect of the fresh exacerbations of endocarditis. The best medication was salicylates of soda in one-gram doses hourly until six doses had been taken or tinnitus occurred. Bromide in moderate doses were helpful and absolute rest was necessary. (5) General Circulatory Failure and Decompensation from Endomyocardial Disease. The fundamental cause of the precordial pain was apparently the nutritional disturbance in the heart itself, consequent upon the circulatory failure. Head's zones were often present. The treatment indicated for the first group was indicated in this one also. (6) Embolic Infarcts in the Main Coronaries and Their Branches. The reader stated that he had studied several cases with intermittent pains lasting days or weeks in whom the symptoms were possibly caused by embolic infarcts of the coronaries of the second or third order. The characteristics common to these cases were temperature, active endocarditis, progressive tendency of the disease, and the presence of local, tender, precordial areas. In this group autopsy findings would be necessary to clinch the diagnosis. (7) Cardiac Lues. This was a very frequent cause of precordial pain. In these cases the pain was usually substernal, dull, boring, and aching in character. It might, however, have the distribution of the types already described. Head's zones were rare. The main pathological changes were found in the aorta and myocardium. Salvarsan combined with the usual mixed treatment was of great value. (8) Premature Arteriosclerosis. This comprised a rare group of cases found in young adults. It was characterized by persistent precordial distress, present often for

months. Gastric symptoms similar to those of hyperacidity might predominate the clinical picture. Physical examination gave no hint of the severity of the pathological process. The cause for such sclerosis was still undetermined, but it was possible that unknown infections and toxemias were the etiological factors. Except digitalis for temporary relief, treatment was of no avail. (9) Tabacism. It was a question whether the tobacco heart should be grouped under organic cardiovascular diseases. The experimental data were inconclusive. The pains might be dull and aching, or sharp and radiating. The first premonition might be very sharp lancinating precordial pains radiating to the left shoulder and forearm and accompanied by unconsciousness. Most of the tobacco pains and arrhythmias ceased when smoking was stopped. Occasionally such pains might recur for years; in such cases nitroglycerin given regularly or with the onset of pains was sometimes of benefit. The author considered this classification by no means complete.

Dr. E. LIBMAN said it was very important not to speak of angina pectoris but to speak of pains in the heart region and try to determine the cause of the pain. Apart from acute and chronic insufficiencies of the myocardium and apart from aneurysms, pericarditis, and syphilitic disease of the heart and aorta, the most common causes of cardiac pain were hypertension, atherosclerosis of the arch of the aorta, and thromboses of the coronary arteries. It had never been determined whether or not in hypertension cases, the pain was due solely to the fact that the heart could not well cope with the strain or whether there was not in such cases also disease of the arch of the aorta involving to a lesser or greater extent the orifices of the coronary arteries. Narrowing of the coronary arteries, either of both or one, was a more common cause for cardiac pain than had been generally believed. Although he was in a position a number of times to suggest such a diagnosis, he had since been informed by Dr. Rolleston of London that the latter's teacher, Dickinson, in his volume of essays, was the first to draw attention to the importance of narrowing or occlusion of the orifices of the coronary arteries by disease of the arch of the aorta. The cause in most instances of the classical picture of angina pectoris, by which they really meant the condition of which a patient was apt to die suddenly, was recent or old thrombosis of the coronary arteries. The diagnosis of a recent thrombosis could often be facilitated by the development of a slight temperature, moderate leucocytosis, and evidence of a patch of pericarditis, all coming on within a couple of days after the attack of severe pain. The diagnosis of old closure of the coronary arteries in patients who might live for years with an organized thrombosis of the coronary arteries, could at times be made from the color of the face. Apart from that it was important to ask whether the patient had any attack which was diagnosed as heart failure or an attack diagnosed as gastritis or ptomain poisoning, which attack was followed by difficulty in walking any distance without the development of cardiac pain. Many cases described as sudden deaths from acute gastritis were cases of thromboses of the coronary arteries. The important symptoms were pressure or pain in the chest, vomiting, and sometimes diarrhea. During the attack the pulse was generally bad, but at times it was remarkably little disturbed. The explanation of cases of so-called angina *sine dolore*, had never been given. Dr. Libman suspected that the absence of pain in such cases was due to the fact that the patients were probably not sensitive to pain. It was important in every case of cardiac pain to determine whether or not the patient was sensitive to pain, and this could be done fairly well by judging of the response which the patient made to strong pressure on the styloid process. Patients who were not sensitive to pain should be much more restricted than other patients as regards exercise, and should be given as little in the way of sedatives as possible, otherwise they were apt to overstep the balance of safety. It was just such patients who were apt to die suddenly without having previously had evidence of the disease. While digitalis was often useful in cases of cardiac pain due to hypertension, it must be used with caution in patients who were suspected of having organic disease of the coronary arteries and should always be tried first in small doses.

Dr. HARLOW BROOKS said he very much regretted that this noteworthy paper had been presented at so late an hour; it seemed an imposition to take up its dis-

cussion as he would have wished. He said he had planned to discuss particularly the phase of pain as a symptom in tobacco poisoning of the heart, since this was a subject in which he had been greatly interested of late, but his material had been taken from him by the statements of Dr. Neuhoof, who precisely agreed with him in his ideas of the so-called tobacco angina; this was not a true organic lesion, but a disturbance of function, probably due to arterial spasm. Another section of the subject in which he was particularly interested was that concerning the occurrence of pain as an evidence of muscle disease in the infections and toxemias. Dr. Neuhoof had pointed out that pain might occur in such instances, irrespective of whether there was hyperarterial tension or not. He emphasized the fact that when it occurred in these conditions without high tension, it was a particularly bad prognostic sign since it indicated either coronary thrombosis or dilatation even under low pressure which was manifestly a much more grave indication of severe muscle disease than when it occurred only with high blood pressure. It was quite possible that to the general medical public the most important fact brought out by the paper was simply that there was such a thing as cardiac pain. The textbooks said little of it, and up to rather recently this very important symptom was either ignored as unimportant except in angina pectoris or was considered as myalgic or even as imaginary. They now knew it to be one of the most important and oftentimes one of the early evidences of cardiac disease. Before actual pain developed it might be prefaced by a sense of weight or weariness in the region of the heart. They should learn to properly appreciate and analyze this symptom.

Dr. LOUIS FAUGERES BISHOP called attention to the great work of Mackenzie, whose book might be called "the bible of cardiology." Mackenzie's explanation of the causes of cardiac pain was very interesting and, if time permitted, would be well worth repeating in connection with this discussion. Dr. Bishop had adopted as his belief that cardiac pain was a protective reflex phenomenon and probably due to similar causes that produced stomachache after eating green apples. In other words, it was the evidence of a hollow muscular organ in trouble. It was a manifestation of disturbance of the function of contractility, either a failure of contractility or a spasm of the muscle. The pain was caused by irritation of the spinal cord and of the nerves passing through the irritated level. A list of the lesions found in patients who had suffered from cardiac pain was only a list of the lesions that would accompany disturbance of the heart muscle, and whatever counteracted the effect of these lesions on the heart muscle or improved the muscle itself would lead to a diminution of pain. Hence, rest to spare the heart muscle, and later exercise to strengthen it, were fundamental elements, as were also suitable nutrition to furnish fuel for the heart's activity and measures directed against any form of toxemia. Dr. Bishop considered digitalis useful in so far as it increased contractility without overstimulating tonicity of the muscle. The nitrites, of course, were useful to reduce the work of the heart temporarily. Mackenzie's functional view of cardiac pain afforded a much more hopeful basis for treatment than the view which attributed it to direct organic influences.

Dr. NEUHOOF said that patients differed in their susceptibility to pain. Indeed, many of the patients who suffered from precordial pains gave histories of having had painful gastric disease in previous years, a fact which might account for the susceptibility of the nervous system to pain arising from cardiovascular disease. The main object of the paper was to study the subject of precordial pains broadly, to gauge the amount of damage to the cardiac musculature, valves, or arteries, and to conserve and therapeutically attack what was still healthy. This seemed a logical method of study and therapy and enabled us at times, despite evident severe cardiac disease, to restore functionally the circulation for a number of years.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 2, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

This meeting was held under the auspices of the Section on Pediatrics.

A Discussion of Acidosis with Special Reference to

That Occurring in the Diseases of Childhood. — Drs. JOHN HOWLAND and W. MCKIM MARRIOTT of Baltimore presented this paper. They stated that the term acidosis was very loosely employed in clinical medicine. It was assumed that the acetone bodies were very abnormal and signified an unusual complication in the course of disease, whereas their presence might be likened to fever, for acetonuria occurred in most of the infectious diseases of childhood with much the regularity that fever did. As hyperpyrexia might in itself be dangerous or fatal so, too, a production of acetone bodies might in itself determine a fatal outcome. It was not the mere presence of acetone bodies that determined acidosis. To understand how acidosis might be brought about, it was necessary to consider the method by which the body maintained its equilibrium in which there was a preponderance of bases over acids. The essayists described in detail the efficient mechanism by which the body guarded against the deleterious influence of acids formed or introduced into the body. These defenses were three in number, acted synchronously, and resided in the blood. They were the increased pulmonary ventilation by which excess of carbon dioxide was removed, leaving a neutral salt, sodium oxybutyrate, or chloride, or what not, to be removed by the second defense, the kidneys. The third method of defense was afforded by the proteins and it depended upon their amphoretic character. The body possessed a further means of defense in that it was able to neutralize acid by the production of alkali in the form of ammonia. It was evident from a consideration of all these facts that there might be all degrees of acid production or retention, as a result of which it was difficult to set a limit and say when acidosis was present. The mere presence of abnormal acids did not indicate that acidosis was present, since they might be entirely compensated for by the various means to which reference had been made. Severe and fatal acidosis might be present when no abnormal acids could be found. The means by which acidosis was recognized were, first, examination of the blood or urine for the presence of abnormal acids, and, secondly, by determining the amount of ammonia secreted in the urine and in its relation to the total nitrogen excretion. A high ammonia coefficient always aroused the suspicion of acidosis, but unless this could be confirmed in some other way it could not be taken as conclusive proof. The methods which they had used in the cases described in this paper were chiefly the determination of the carbon dioxide in the alveolar air, Sellard's test, the alkali tolerance, the determination for the hydrogen ion concentration of the serum and the oxygen combining power of the hemoglobin. The essayists described each of these methods and showed why it was useful as a measure of over-production or of retention of acids in the body. In childhood acidosis resulting from the production of abnormal acids was found chiefly in diabetes and in recurrent vomiting. A study of diabetes in children shows very well the enormous amount of acid that might be taken care of with no disturbance of the reaction of the blood and with no effect upon respiration. In recurrent vomiting the conditions were more obscure and less understood than in diabetes. He had made observations on two cases of recurrent vomiting, a mild and a fatal one, in one of which the acidosis was clearly due to acetone bodies in the blood. They had studied chiefly the acidosis occurring in the diarrhea diseases of infancy and had found that infants with the severe diarrhea of infancy might die with no evidence of acidosis whatever. This was true of the majority. On the other hand, a number of infants with severe diarrhea did develop evidence of acidosis, and the overwhelming majority of these died. The clinical evidence of the acidosis was hyperpnea. When there had been deep labored breathing without cyanosis they had always been able to obtain other proof of acidosis. They had found a low carbon dioxide tension of the alveolar air by the use of Plesch's method modified so that it was applicable for use in infants, and Dr. Howland said he believed that they were the first to be successful in measuring the carbon dioxide tension in infants. They had found that the tension of the air in normal infants varied between 35 and 42 mm. while in acidosis it was less than this, frequently between 15 and 25 mm. With infants showing such a low carbon dioxide tension the Sellard's test was positive. There was also a great tolerance for alkali in such infants so that relatively large amount had to be administered in order to change the reaction of the urine. In all the severe cases the reaction of the

blood by the indicator method had shown a distinct shifting of the reaction in the direction of acidity. This reaction might again become normal on giving alkalis in sufficient quantities. Finally, evidence had been obtained of an alteration in the reaction of the blood by determining a great lowering of the combining power of hemoglobin. With reference to the question as to what produced this acidosis, the essayists stated that uncompleted studies made in their laboratory seemed to indicate that potential alkali was not lost in the diarrheal stools. At the present time it could not be maintained that an excess of sodium or potassium in the stools showed acidosis. In seeking for further explanation for the production of acidosis they had observed that there was one striking symptom of the severe acidosis of infancy and that was the diminution of the output of urine. Complete anuria was by no means unusual. In the present state of their knowledge this seemed to offer an explanation of the accumulation of acids and they were still studying this phase of the question. From a review of the cases presented it might be said that acidosis was not uncommon in infancy and childhood. It was especially frequent in the severe diarrhea of infancy, but it might appear in a variety of diseases, and sometimes alone. Its recognition in older children was not difficult; the character of the respiration was usually sufficient to arrest one's attention, and one or two relatively simple laboratory tests would quickly determine the question. Older children reacted promptly and sometimes permanently to alkali therapy. In infants it might be possible to stop the laboratory and clinical evidences of the condition, but they usually died. For this reason in the severe diarrhea of infancy one should not wait until acidosis had developed but should give bicarbonate of soda from the beginning in sufficient quantities to render the urine alkaline and to keep it so. The alkalis might be administered by mouth, by rectum, subcutaneously, or intravenously. The latter was the method of choice when rapidity of action was desired, and in acidosis rapidity of action was always desirable. If facilities for intravenous injection were not at hand, a subcutaneous injection might be given. For the intravenous injection a 4 per cent. solution was employed and for the subcutaneous a 2 per cent. solution, the amount being gauged to meet the individual indications. As much as 10 grams in 24 hours might be required.

Dr. DONALD D. VAN SLYKE stated that their experience had been in complete agreement with that of Drs. Howland and Marriott. Some interest, however, might attach to a definition of acidosis from the standpoint of the chemist. Such a definition would be as follows: "Acidosis is a condition in which an accumulation of acids occurs in the body, and which results from the failure of elimination to keep pace with the production of acids." Acidosis might result, as in diabetes, from an overwhelmingly rapid production of acids, with which even a normal eliminating mechanism could not keep up, or it might, as in some cases of nephritis, result from failure of the eliminating mechanism to dispose of even the amount of acid formed in the ordinary metabolism. Whatever the cause the direct result was that the bicarbonate content of the body fluids was lowered. Because of this fact the determination of the bicarbonate content of the blood plasma was the most direct method for the determination of the presence and degree of an acidosis. The severity of acidosis was proportional to the fall below normal of the bicarbonate content of the plasma. The most reliable method for estimating the bicarbonate content of the blood was the direct determination of the plasma bicarbonate. This was done by acidifying a known volume, usually 1 c. c. of plasma, and measuring the amount of carbon dioxide gas which was set free. By this method they found that in the normal adult carbon dioxide gas equal to 55 to 75 volume per cent. of the plasma from which it was set free. When this fell to 30 per cent. acidosis became dangerous, when below 30 per cent., in an adult, acidosis was serious, and as low as 20 per cent. it seemed nearly certain to be fatal. The estimation of the alveolar carbon dioxide owed its value to the fact that it was an indirect measure of the carbon dioxide content of the plasma. In order to keep the hydrogen ion concentration of the plasma at its proper level the respiratory center maintained the ratio between the amount of carbon dioxide in the form of free carbonic acid and bicarbonate, respectively, at one to twenty. Thus a normal plasma contained 60 volume per cent. of bicarbonate carbon dioxide, and three volume per cent. of carbon dioxide

dissolved as free carbonic acid. If acids accumulated sufficient to reduce the bicarbonate carbon dioxide to 30 per cent., respiration and circulation were so stimulated that the carbonic acid carbon dioxide was reduced to one and one-half per cent. If the bicarbonate carbon dioxide was reduced one-half, the respiratory mechanism reduced the carbonic acid carbon dioxide of the plasma also to one-half, and the physical laws of gas solubility also reduced the percentage of carbon dioxide in the alveolar air by half. As to the accuracy of this indirect measure their experience had been that in normal individuals the alveolar carbon dioxide indicated within a limit of error of about one part in five the level of the plasma bicarbonate. They had found that the same limit of error held for diabetics; so that this method was of use in diagnosing diabetic acidosis when it was not desirable to draw blood for the direct examination. In certain other pathological conditions this was no measure at all of the plasma bicarbonate since it was dependent upon the normal function of the entire respiratory and circulatory apparatus. The alkaline tolerance test as used by Sellards, Henderson, and Palmer might also be considered an indirect measure of the plasma bicarbonate. The amount of bicarbonate which must be administered in order to turn the urine alkaline was directly proportional to the extent to which the bicarbonate content of the body fluids had fallen below this point. As the alveolar carbon dioxide test depended upon the normal function of the respiratory mechanism, so the alkaline tolerance test depended upon normal kidney function. The determination of the hydrogen ion concentration of the blood by even the most accurate methods now available appeared to be of less value than any of the methods just referred to; it afforded only a tardy warning of the development of acidosis. In cases in which acidosis was caused by retarded elimination the urine gave especially fallacious indications of the condition of acidosis. A patient might be sinking in acidosis steadily toward coma, with only normal excretion of acids and ammonia, and he might begin to recover, when this excretion would become increased. They had had a case in which the urinary findings alone would have led to conclusions exactly opposite to the truth as to the direction in which the patient was progressing. The significance of urinary findings should not be minimized, but the fact remained that they did not show whether acids were accumulating within the organism or not.

Dr. GRAHAM LUSK said there were two forms of organic acids produced from the metabolism of food-stuffs, the acetone bodies, represented by beta-hydroxybutyric acid and carbohydrates, and lactic acid. Dr. Howland had spoken of the possibility of there being other organic acids than beta-hydroxybutyric acid, and it might be interesting to suggest the possibility of the formation of lactic acid in the cases he had cited. Lactic acid had been found to be a constant constituent of the human blood after exercise and after ascending high mountains. In dogs it appeared in the blood after cramps produced by strychnine and after phosphorus poisoning. That the lactic acid which was produced under these and similar conditions was derived from glucose followed from the fact that if one gave strychnine to a depancreatized diabetic dog, violent convulsions ensued without and production of lactic acid, and if one produced phlorrhizin glycosuria in a dog poisoned with phosphorus, lactic acid disappeared from both blood and urine. Munzer and Loewy, in 1901, administered sodium bicarbonate to dogs poisoned with phosphorus and in consequence ammonia almost disappeared from the urine indicating that the urea forming function was normal. In many ways the children described by Dr. Howland recalled the behavior of the dogs poisoned with phosphorus. Possibly a search for lactic acid in this disease as well as in other pathological states involving acidosis when the acetone bodies were absent, might lead to some information on this subject.

Dr. L. EMMETT HOLT said he wished to emphasize what Dr. Howland had said with reference to the frequency of acetone in the urine of children, often without any clinical significance. One of the members of the house staff of the Babies' Hospital examined 200 consecutive urines in young children and found that acetone was present in 30 per cent. of the cases. It was present in 70 per cent. of those suffering from lobar pneumonia. Frequently when the urinary analysis showed the presence of acetone the physician concludes that his patient was in a serious condition because of this finding, while it was usually of no importance. Again, there might be a serious acidosis present with very slight or no

evidence so far as the acetone bodies in the urine were concerned. Three determinations were made in a series of cases at the Babies' Hospital, namely, the ammonia nitrogen content of the urine, the carbon dioxide combining power of the blood, and the acetone in the urine. The ammonia nitrogen in the urine ran quite parallel with the carbon dioxide combining power of the blood, but there was no constant relation between these two and the acetone in the urine. Dr. Holt called attention to the occurrence of acidosis in infants fed for a long period of time on very high percentages of fats. Such children might go on well for a time, when an acute upset occurred with symptoms of marked acidosis, due probably to loss of bases from the body in combination with the fats in the stools. Cases of severe diarrhea with marked acidosis were nearly always fatal, hence there was need of means by which the acidosis might be recognized early by the practicing physician. Dr. Van Slyke's test for the carbon dioxide combining power of the blood seemed the most practical for clinical use, since it could be made with 1 c. c. of blood, and with proper apparatus the test could be made in twenty minutes. Emphasis should be placed on the danger of acidosis in children kept for a long time on a one-sided diet, and upon the necessity of getting back (when because of serious disturbance of digestion an absurd diet has been used) as soon as possible to one in which all the elements of food were properly represented.

Dr. OSCAR M. SCHLOSS said that his experience with acidosis had been confined almost entirely to intestinal intoxication in young infants. In a small group of such cases he had determined the carbon dioxide content of the blood, the ammonia content of the urine, and the tolerance to sodium bicarbonate. The results of the tests were in accord with those of Dr. Howland and Dr. Marriott. The relatively slight importance of acetone and diacetic acid in the urine was well illustrated in a few cases in which, despite a great reduction of the carbon dioxide of the blood and increased tolerance to sodium bicarbonate, the urine contained no acetone or diacetic acid. The uncertainty of the urinary ammonia as an index to the presence or degree of acidosis to which Dr. Howland had referred had proven true in several of his cases, and was in accord with an experiment of Sherman and Gettler. They found that when a subject was fed on a diet productive of high acidity, only a relatively small proportion of the calculated acid appeared in the urine combined with ammonia, while the greater portion was excreted as acid or acid salts. In this connection it was perhaps of interest that the ash of cow's milk had relatively slight basic properties. The cases of intestinal intoxication with marked dyspnea which were admitted to the service of Dr. La Fetra at Bellevue Hospital during the past summer were treated by the administration of large doses of sodium bicarbonate given by subcutaneous or intravenous injection, by mouth, or by the Murphy drip method. There were 42 patients treated, of whom 31 died; four recovered completely; three left the hospital in an improved condition, and three were taken home unimproved. The fatal cases were of interest in that 16 of the 31 showed very marked improvement. The dyspnea ceased and the general condition of the patient was much improved, so that they all felt that recovery was probable. Death was usually due to a recurrence of the intoxication which appeared suddenly and was of short duration. It seemed to them that the alkali relieved the symptoms of intoxication but was without influence on the underlying nutritional disorder.

Dr. HERMAN SCHWARZ considered three types of acidosis. The first he said was secondary to a gastroenteric condition. The second one was commonly called recurrent or periodic vomiting, and the third type followed or occurred in conjunction with infectious diseases, especially grippe. The last form was secondary usually to an infection of the nasopharynx and had a tendency to recur with other attacks of nasopharyngitis, and was thus mistaken for the true form of periodic vomiting. An interesting differential point was the polymorphonuclear leucocytosis, which occurred in the infectious type and a lymphocytosis which was present in cases of true cyclic vomiting, either during the attack or in the interval. Dr. Schwarz said he had studied these three types from the standpoint of the blood sugar content and from the way the blood sugar reacted upon the administration of sugar to these children. The blood sugar content might either be normal, or, when sugar was present in the urine, there

might be a hyperglycemia. In the normal child or adult, when glucose was given four to six hours after a meal an immediate increase in the blood sugar could be noted. This increase rose rapidly, usually well within the first hour, and before two and one-half hours had elapsed the blood sugar content had again reached what it was before the administration of the sugar. With these cases of acidosis, curiously enough, the same rapid rise was noted immediately after the administration of the glucose, but after three or four hours or more, the blood sugar might be much above what it was before the administration of the sugar. Impairment of the kidney function might explain this since it would prevent the elimination of the sugar by the urine or, as had been shown by Dr. Epstein, the ability of the liver and muscles to build up glycogen was either impaired or lost. It was also observed that these patients would retain the glucose when they vomited everything else, and again the acetone and diacetic acid in the urine immediately disappeared for some hours. Some of these patients were given casein and by this means the acidosis could be made to disappear. Vegetable protein was also tried with success, but this was not chemically pure.

Dr. WILDER TILESTON of New Haven, Conn., said he would like to call attention to the contrast between the effects of the same degree of acidosis as measured by the carbon dioxide tension of the alveolar air under different circumstances. Thus the English observers Kennaway, Pembrey, and Poulton found in diabetes a day or two before the onset of coma a sudden drop to 18 or 14 mm.; they considered values below 25 mm. to indicate a grave condition in this disease, and those below 20 mm. to foreshadow imminent coma. On the other hand, Haldane, Henderson and Douglass, at the top of Pike's Peak (14,000 feet) found that the carbon dioxide tension dropped to 18 or 20 mm. as the result of the high altitude, without any serious effects. In starvation Benedict found a tension of 26 mm. It was evident that the gravity of the situation did not depend entirely on the degree of the acidosis, but partly on the underlying cause. With reference to the relation of dyspnea to acidosis Lewis and his coworkers recently described a type of dyspnea without cyanosis, occurring in elderly people with cardiorenal lesions, in which they found a high degree of acidosis. Nocturnal attacks of dyspnea and Cheyne-Stokes breathing were common. In young patients with uncomplicated cardiac insufficiency, although dyspnea was present, there was no acidosis. Evidently the state of the respiratory center was also of importance for Peabody found a high degree of acidosis in the terminal stages of uremia without dyspnea, and Benedict in a man undergoing a prolonged fast found marked acidosis without any increase in the total ventilation. Also Haldane and Henderson found on Pike's Peak that with acclimatization the dyspnea disappeared, although the low tension of the alveolar carbon dioxide persisted even after descending to a lower level.

Dr. ABRAHAM JACOBI said they had been told by Dr. Howland that there was little likelihood of successfully treating these cases of severe diarrhea with acidosis, and they had just heard that a large number of these patients died, hence it seemed fitting to speak of prevention. What Dr. Howland had said in connection with the overfeeding of fats was correct. One cause of acidosis and diarrhea was excessive feeding of fats. There were some doctors who could not overcome this tendency to overfeed with fats. Another habit of which many men could not break themselves was that of feeding milk sugar. Babies should not be fed on milk sugar to the extent that they had been. Dr. Jacobi said he never used milk sugar, and it should not be used unless in very small quantities, because babies got enough milk sugar in their milk foods. A third point was that milk should not be given without carbohydrates (barley or oatmeal water). If they would be careful of fats, be careful of milk sugar, and remember what he had said about carbohydrates acidosis would be prevented and they would keep away from a number of death certificates.

Dr. W. McKIM MARRIOTT said that in the discussion of the paper the acetone bodies had received considerable attention and that chiefly to minimize their importance. It was to be clearly understood that the acetone bodies in themselves were not essentially toxic and that they could prove harmful to the body only by removing the bases. The appearance of the acetone bodies in the urine in large amounts was of course evidence that there had been a large production in the

body, but may have been completely compensated for by the defenses of the body. In examining the blood for acetone bodies one was enabled to determine how much acid had accumulated and an accumulation of acid indicated that the kidneys were not excreting the acid as fast as it was being formed, and that a considerable base of the blood had been claimed by the abnormal acid and that therefore a considerable amount of alkali must be administered to supply the deficit. The result of the administration of the alkali in such cases was usually to increase the excretion of acetone bodies in the urine and at the same time to diminish the concentration in the blood, this being coincident with the improvement in the clinical condition of the patient. Dr. Lusk had mentioned lactic acid as a possible cause of the acidosis in the nutritional disorders in children. Following his suggestion they had been looking for excessive lactic acid production in these children. With the methods available they had not as yet been able to state positively whether lactic acid entered in as a factor or not. Dr. Marriott said he wished to make it very clear that in the diarrheal diseases of children acidosis was not in itself necessarily the cause of death in most cases. In many cases the acidosis was in itself, however, sufficiently grave to determine a fatal outcome. By curing the acidosis they did not cure the primary disease, since death might, and usually did, occur from the primary condition. The indications, however, for treating the acidosis were perfectly definite. By curing the acidosis one factor which might be responsible for death was removed; and in the primary disease which they were considering the primary disease was essentially temporary and curable as compared with diabetes or nephritis. The detection of acidosis was not difficult. The most easily recognizable indication was an acyanotic dyspnea, or, more correctly, hyperpnea. Perhaps the simplest laboratory test that could be applied and one which gave valuable information by detecting the slightest degree of acidosis was the determination of the carbon dioxide tension of the alveolar air. This method had hitherto not been adapted to clinical use as a more or less elaborate gas analysis apparatus had been necessary. They had modified the method so that the gas analysis apparatus might be dispensed with and the determination might be carried out in a few minutes by a person without laboratory training. They had also recently modified the indicator method so that one could determine by it not only the actual hydrogen ion concentration which gave evidence of a severe grade of acidosis, but also the bicarbonate reserve of the blood and the carbon dioxide tension. This method further served to differentiate between an acidosis due to carbon dioxide and one due to volatile acids. No complicated apparatus was required. Finally, the experimental administration of an alkali served both as a diagnostic and a therapeutic measure. As an illustration of the value of these methods, during the past week one of the workers in the pediatric clinic had detected the presence of a severe grade of acidosis in two patients suffering from a condition in which, so far as they were aware, acidosis had not hitherto been suspected. In summing up it might be said that acidosis was a very grave pathological condition of frequent occurrence. It was readily detected. The therapy was specific, namely, alkalies.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE TEXAS STATE BOARD OF MEDICAL EXAMINERS.

June 22, 23, and 24, 1915

ANATOMY.

1. Give the location and shape of the frontal bone, and name the bones with which it articulates.
2. What structures are used in the formation of an articulation, and what three classes of articulations are there?
3. Name the triangles of the neck and their subdivisions, and give boundaries of each.
4. Describe the diaphragm and give origin and insertion.
5. Give location of the subclavian arteries and tell origin of.
6. Give origin and distribution of the pneumogastric nerve.

7. Where does the liver get its blood supply?
8. Give abdominal surface location of the gall-bladder and appendix.
9. What constitutes the sympathetic nervous system?
10. Describe and give location of the inguinal canal.

PHYSIOLOGY.

1. Define physiology.
2. Name the elementary tissues.
3. Name the kinds of muscular tissue.
4. Describe briefly the blood.
5. What is an "internal secretion"? Name five organs which have such.
6. If the pneumogastric nerves were severed, what would be the effect on the heart?
7. Where are the plexuses of Auerbach and Meissner located? Their function?
8. Where are the Malpighian bodies found? State their function.
9. Name the organs of excretion in order of their importance.
10. Where are the cardioinhibitory and cardioaccelerator centers located?

CHEMISTRY.

1. What is an element? A compound? An example of each.
2. Define a deliquescent salt; efflorescent salt.
3. In Marsh's test for arsenic, how do you differentiate arsenic from antimony spots?
4. (a) Give a process for making chlorine gas. (b) Give properties of chlorine gas. (c) Of what value is this gas?
5. What is an acid? What is a base? Complete the equation $2\text{NaCl} + \text{H}_2\text{SO}_4$.
6. Define normal salt, basic salt, acid salt.
7. Describe iodine as found in the market. (b) Test for iodine.
8. How is chloral hydrate prepared? (b) Physiological properties of chloral hydrate.
9. From what source do we obtain pure genuine salicylic acid?
10. Give test for morphine sulphate.

HISTOLOGY.

1. Name and describe membranes of brain.
2. Give the structure of human skin.
3. Locate and give structures of Peyer's patches.
4. Give structure of the thyroid gland.
5. Give a histological difference between pyloric and cardiac ends of stomach.
6. Give the development of bone.
7. Draw cross section of spinal cord at tenth dorsal, and name findings.
8. Give histological difference between veins and arteries.
9. Give histological structure of lymphatic gland.

BACTERIOLOGY.

1. Describe the Wassermann reaction.
2. Define alexins, agglutinins, and precipitins.
3. Define diapedesis, phagocytosis; of what use is the process of phagocytosis in the human system?
4. State names of the stains used to demonstrate the presence of the following microorganisms: staphylococcus, streptococcus; the negri bodies of hydrophobia.
5. State methods of making a culture of the Klebs-Loeffler bacillus.
6. Define toxins, endotoxins, and autotoxins.
7. Give morphology of pneumococcus and the parasite of malaria (any variety).
8. Describe the Widal reaction and von Pirquet's method of cutaneous diagnosis of tuberculosis.
9. What pus-producing microorganism causes the greatest mortality, and give names of principal diseases in which it is a principal cause of destruction.
10. Define flagellated and name all the flagellated pathogenic organisms.

OBSTETRICS.

1. Give the symptoms and management of puerperal infection.
2. Give the blood supply of the uterus.
3. What are the changes that take place in the circulatory apparatus of the fetus after birth?
4. Give differential diagnosis between uterine fibroma and pregnancy.
5. Give indications for use of forceps and for cesarean section.
6. Give the hygiene of pregnancy.

7. Name three of the most frequent diseases to which pregnancy predisposes, select one and give symptoms of same.

8. Give three indications for induction of premature labor and describe one method of performing the same.

9. Give the proper treatment of ophthalmia neonatorum.

10. Give the definition of premature labor and abortion.

GYNECOLOGY.

1. Outline your scheme for taking a gynecological history.

2. (a) What are the advantages and disadvantages of Pfannenstiel's incision? (b) Enumerate in order of importance the causes of metrorrhagia.

3. Describe a standard perineorrhaphy (secondary).

4. What precautions should be taken in making a vaginal examination of a virgin?

5. A married woman, aged 40 years, with one child, aged 14 years, and no subsequent pregnancies, is in good health until suddenly seized with violent pain in left lower abdomen and collapses; suggest two diagnoses.

6. Criticise ventrofixation and ventrosuspension uteri.

7. What conditions justify double ovariectomy?

8. What surgical procedure would you advise to correct procidentia with cystocele and rectocele in a woman 50 years of age?

9. Name the contraindications of uterine curettage.

10. Would you leave the appendix, in abdominal operations for other conditions? Reasons for your answer.

ANSWERS.

ANATOMY.

1. The *frontal bone* is located at the anterior part of the cranium; its shape is that of a cockle-shell; it articulates with the two parietal, the sphenoid, the ethmoid, two nasal, two superior maxillary, two lacrymal, and two malar bones.

2. *Structures entering into the formation of a joint*, are: Bone, cartilage, fibrocartilage, ligament, and synovial membrane.

The *three forms of articulations* are: (1) *Synarthrosis*, or immovable articulation, such as that between the two parietal bones. (2) *Amphiarthrosis*, or mixed articulation, such as that between the two pubic bones. (3) *Diarthrosis*, or freely movable articulation, such as that between the humerus and the ulna.

3. The *ANTERIOR TRIANGLE OF THE NECK* is bounded: *In front* by a line from the chin to the sternum; *behind* by the anterior margin of the sternomastoid; *base* is upward, and is formed by the lower border of the body of the lower jaw and a line from the angle of the jaw to the mastoid process. It is *divided* into three smaller triangles (inferior carotid, superior carotid, and submaxillary) by the digastric muscle and the anterior belly of the omohyoid. The *inferior carotid triangle* is bounded, *in front* by the median line of the neck; *behind*, by the anterior margin of the sternomastoid; and *above*, by the anterior belly of the omohyoid. The *superior carotid triangle* is bounded, *behind* by the sternomastoid; *below*, by the anterior belly of the omohyoid; and *above* by the posterior belly of the digastric. The *submaxillary triangle* is bounded, *above* by the lower border of the body of the mandible and a line drawn from its angle to the mastoid process; *below*, by the posterior belly of the digastric and the stylohyoid; and *in front*, by the anterior belly of the digastric.

The *POSTERIOR TRIANGLE OF THE NECK* is bounded: *In front* by the sternomastoid; *behind*, by the anterior margin of the trapezius; and its *base* corresponds to the middle third of the clavicle. It is *divided* into two smaller triangles (the occipital and the subclavian) by the posterior belly of the omohyoid. The *occipital triangle* is bounded *in front*, by the sternomastoid; *behind*, by the trapezius; and *below*, by the omohyoid. The *subclavian triangle* is bounded *above*, by the posterior belly of the omohyoid; *below*, by the clavicle; and *in front*, by the sternomastoid.

4. The *diaphragm* is a musculofibrous septum which divides the thoracic from the abdominal cavity; it is fan-shaped; the broad elliptical portion is horizontal, and the crura are vertical. It is attached to the ensiform, to the internal surfaces of the lower six costal cartilages, to bodies and intervertebral substances of first, second, and third lumbar vertebrae. Its *openings*

are: (1) The aortic, transmitting the aorta, vena azygos major, and the thoracic duct; (2) the esophageal, transmitting the esophagus, pneumogastric nerves, and some small esophageal arteries; (3) the opening for the vena cava, transmitting the inferior vena cava, and small branches of the right phrenic nerve; (4) the right crural, transmitting the right splanchnic nerves; (5) the left crural, transmitting the left splanchnic nerves and the vena azygos minor.—*Nerve Supply*: Phrenic, lower intercostals, and sympathetic.

5. *Subclavian artery* arises on the right side from the innominate artery, on the left from the arch of the aorta; and it passes outward, arching over the pleura, lying on the first rib, between the scalenus anticus and medius, and ends at the lower border of the first rib. It is divided into three parts by the scalenus anticus; the first part being from the origin of the artery to the inner border of the scalenus anticus; the second part, posterior to that muscle; and the third part from the outer edge of the muscle to the lower border of the first rib.

6. *Pneumogastric nerve*. *Superficial origin*: Groove between restiform and olivary bodies. *Deep origin*: Nuclei in floor of fourth ventricle. *Distribution* is shown by the names of the branches: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary, esophageal, and gastric.

7. The *blood supply of the liver*: Hepatic artery and hepatic veins; the portal vein also conveys blood to the liver.

8. The *gall-bladder* is situated in a fossa on the under surface of the right lobe of the liver. It is in relation, in front, with the anterior abdominal wall, immediately below the ninth costal cartilage.

Relations of vermiform appendix. Owing to the variable position of the appendix, these are not definite. As a rule, the appendix is given off from the lower, posterior surface of the cecum, and points upward and to the left, but it may hang down into the pelvic cavity, or take almost any other position with reference to the lower end of the cecum. The point at which the appendix joins the cecum is generally indicated on the anterior abdominal wall by *McBurney's point*. (A line is drawn from the anterior superior spine of the ilium to the umbilicus, and a point is marked off on this line at a distance of two and a half inches from the spine of the ilium.)

9. "The *sympathetic nervous system* consists of (1) a series of ganglia connected together by a great ganglionic cord, the gangliated cord, extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller or terminal ganglia, situated in relation with the abdominal viscera; and (4) of numerous fibers."

10. The *inguinal canal* is an oblique canal situated a little above and running parallel with Poupart's ligament. It is from an inch and a half to two inches in length, runs downward and inward, and extends from the internal abdominal ring to the external abdominal ring.

Its *boundaries* are: *In front*: the skin, superficial fascia, aponeurosis of the external oblique, and (for its outer third) the internal oblique. *Behind*: the conjoined tendon, the triangular fascia, the transversalis fascia, subperitoneal fat, and peritoneum. *Above*: the fibers of the internal oblique and transversalis. *Below*: Poupart's ligament and the transversalis fascia.

Contents: the spermatic cord in the male, and the round ligament in the female.

PHYSIOLOGY.

1. *Physiology* is that branch of science which treats of the functions of living tissues and organisms in a state of health.

2. The *elementary tissues* are: Epithelial, connective, muscular, and nerve tissues.

3. *Varieties of muscle tissue*: (1) Voluntary striated muscle; (2) involuntary, non-striated muscle; (3) involuntary striated or cardiac muscle.

4. The *physical properties of blood*: Fluid, somewhat viscid, red; specific gravity, from 1055 to 1062; alkaline reaction; saltish taste; characteristic odor; variable temperature (average, about 100° F.).

The *constituents of the blood* are plasma and corpuscles. The *plasma* consists of water and solids (pro-

teids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leucocyte, lecithin, histon, etc.)

The *red blood corpuscles* are biconcave discs, about 1-3200 of an inch in diameter; they are non-nucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin.

Their function is to carry oxygen from the lungs to the tissues.

The white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain: it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

There are also *platelets*, which are very small, colorless, irregular shaped bodies; they are about one-fourth the diameter of a red corpuscle. Their function is not determined; it is possible that they take some part in the coagulation of the blood. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood.

Plasma conveys nutriment to the tissue: it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

5. *Internal secretions*: It is generally held now that the glandular organs, chiefly the pancreas, liver, and the ductless glands, produce a secretion, peculiar in each case to the particular gland producing it, and which is supposed to be given off to the blood or lymph, and to have some peculiar value in the general metabolism of the body. Such secretions are called internal secretions, in contradistinction to the previously known secretions, which are carried off by a duct, and are known as external secretions. Very little is definitely known of these internal secretions, but much work is being done on the subject.

Internal secretions are produced by the liver, pancreas, ovaries, testes, thyroids, parathyroids, spleen, suprarenals, pituitary body, and by the fetus.

6. If the pneumogastric nerves were severed the heart would beat more rapidly, as the inhibitory impulses would no longer reach the heart.

7. *Auerbach's plexus* is situated in the walls of the intestine between the circular and longitudinal muscle fibers.

Meissner's plexus is situated in the submucous coat of the intestine.

Their function is to cause intestinal peristalsis.

8. The *Malpighian bodies* are found in the cortical portion of the kidneys; their function is to excrete the water, salts and urea which are eliminated in the urine.

Malpighian bodies are also found in the spleen; their function is the formation of lymphocytes.

9. The *organs of elimination* are: (1) The *skin*, which eliminates water and a slight quantity of carbon dioxide, urea, and salts; (2) the *lungs*, which eliminate water, carbon dioxide; (3) the *intestines*, which eliminate the indigestible and unabsorbed substances from the food, with secretions from liver and pancreas; (4) the *kidneys*, which eliminate water, urea, and other nitrogenous matter, and inorganic salts.

10. The *cardioinhibitory* and *cardioaccelerator centers* are situated in the floor of the fourth ventricle.

CHEMISTRY.

1. An *element* is a kind of substance which we can-

not, by any known means, split up into any two or more other kinds of substance; as oxygen.

A *compound* is a substance made up of two or more elements, chemically united, in definite proportions; as sulphuric acid.

2. A *deliquescent salt* is one that has a tendency to unite with water which it absorbs from the air, becoming damp, and finally liquid.

An *efflorescent salt* is one which, on exposure to air, loses its water of crystallization and becomes a powder.

3. The *arsenical stain*: (1) Volatilizes readily in an atmosphere of hydrogen, and (2) the escaping gas has the odor of garlic; (3) when heated in a current of oxygen, octahedral crystals are formed; (4) it dissolves promptly in a solution of sodium hypochlorite.

The *antimonial stain*: (1) Requires a much higher temperature for its volatilization, and (2) the escaping gas has not the odor of garlic; (3) when heated in a current of oxygen, an amorphous powder is formed; (4) it is insoluble in a solution of sodium hypochlorite.

4. Chlorine gas may be made by heating together manganese dioxide and hydrochloric acid:

Chlorine gas is a greenish yellow gas, with a penetrating and very irritating odor; in the presence of moisture it is a bleaching agent; it combines readily with other elements, and frequently combines with the evolution of light and heat; it is a disinfectant. Its value lies in its bleaching and disinfecting properties.

5. An *acid* is a compound of an electronegative element or residue with hydrogen, part or all of which hydrogen it can part with in exchange for an electropositive element, without the formation of a base.

A *base* is a ternary compound which is capable of entering into double decomposition with an acid, to form a salt and water.

6. A *normal salt* is one in which all the replaceable hydrogen of the acid has been replaced.

A *basic salt* is a compound made up of a normal salt and the hydroxide or oxide of a metal.

An *acid salt* is one in which only a part of the replaceable hydrogen of the acid has been replaced.

7. *Iodine* is a bluish-gray solid, in crystalline scales, with a metallic luster; it is volatile, and has a peculiar odor; it is very slightly soluble in water.

Free iodine colors starch paste a dark violet-blue.

8. *Chloral hydrate* is prepared by mixing together equivalent parts of chloral and water.

It is a colorless, transparent, crystalline solid, with a penetrating and aromatic odor, and a caustic taste; it slowly volatilizes when exposed to the air, and is freely soluble.

9. *Salicylic acid* is obtained synthetically from phenol; it exists naturally, in combination, in oil of wintergreen.

10. Solution of neutral ferric chloride gives a blue color with morphine.

HISTOLOGY.

1. *The Membranes of the Brain*.—"The *Dura* is a tough membrane composed of interlacing bundles of white fibrous and yellow elastic tissues that contain lymph spaces between them. Within the skull, it forms the inner periosteum of the cranium, which relation ceases at the foramen magnum, the entrance into the vertebral canal. This membrane is lined by endothelial cells, and forms the outer boundary of the subdural lymph space. It is quite vascular, and a few nerves, that pass to the blood spaces are found. The *Arachnoid* is a thin, delicate, weblike membrane composed of loosely interwoven bundles of white fibrous tissue. It lies closely applied to the *dura*, and is separated from the *pia* by the subarachnoid lymph space. This is also lined by endothelial cells. It forms the *Pacchionian* bodies and villi, but contains neither blood vessels nor nerves. The *Pia* is the vascular membrane. Its outer portion contains the bulk of the vessels, while the inner enters into close relation with the nerve tissue. Its blood vessels lie in the fibro-elastic network, surrounded by perivascular lymphatics. Its arachnoid surface is covered by endothelial cells. Only a few nerve fibers are present. The *pia* is the only one of these membranes that follows the fissures and depressions of the nerve system."—(Radasch's *Histology*.)

2. "The *skin* is composed of two parts, the *epidermis* and *cutis vera*. The *Epidermis* consists of stratified squamous epithelium, the *cutis vera* of fibrous tissue. Processes of these interdigitate. The deeper layers of the *epidermis* are soft, and constitute the *rete mucosum*,

or stratum Malpighii. The cells of the deepest layer are columnar in shape, and in dark races they contain pigment. In the layers above the cells become polygonal or rounded. Narrow clefts between the cells are bridged by fine protoplasmic processes (prickle cells). The superficial layers are horny. In the layers of cells (stratum granulosum) next the stratum Malpighii granules of a substance called "eleidin" accumulate. In the layers superficial to this (stratum lucidum) the cells contain large droplets of a similar substance (kerato-hyalin), which tend to run together and obscure the characters of the cells and render their outline indistinct, giving the layers a clear appearance. The surface layers take the form of long, thin, flat cells, whose nuclei have been obscured by kerato-hyalin. These constitute the stratum corneum. Cells of the surface layer are always being lost, and are replenished from the cells of the deeper layers. The young cells formed in the deep layers push the older cells toward the surface, and as they pass outward the cells begin to accumulate granules, and then become transformed to the type found in the stratum corneum. The *Cutis Vera* is composed of dense fibrous tissue, which rises up into papillæ, indenting the epithelium. In the deeper part the fibrous tissue becomes looser, and merges indefinitely into the reticular tissue of the subcutaneous layer. In the papillæ are loops of capillary vessels, and in the palm and sole there are tactile corpuscles. Bloodvessels form a capillary network near the surface of the true skin, and send up loops into the papillæ and supply branches to the hairs, sweat glands, etc.; but vessels do not pass into the epidermis. Nerves pass into the Malpighian layer, and some of the varicose branches form flattened menisci between the layer of cells. Medullated nerves end in touch-corpuscles in the fibrous papillæ."—(*Aids to Histology*.)

3. *Peyer's patches* are aggregations of solitary glands, measuring from about half an inch to three inches in length; they are found mainly in the ileum, but also occur in the duodenum, and jejunum; they are situated lengthwise in the intestine, and are located opposite to the mesenteric attachment. Each patch is surrounded by a group of the crypts of Lieberkühn. There are said to be from 30 to 50 of these patches in the human intestine. As a rule, they have no villi on their surface.

4. The thyroid gland "is surrounded by a capsule that sends in trabeculæ, which divide the gland into lobes and lobules. These divisions are irregular, and the lobules are composed of a number of short tubules, sometimes called follicles. Each tubule is lined by cuboidal epithelial cells that rest upon a basement membrane; outside of this is the intralobular, or intertubular, connective tissue that supports the blood-vessels. In the tubules is seen a peculiar, homogeneous substance, the colloid substance, that is supposedly the result of the activity of the cells. It has a yellowish color, and as blood cells are frequently seen in it, the color may be due to the hemoglobin from these."—(*Radasch's Compend of Histology*.)

5. "The chief difference between the pyloric and cardiac regions of the stomach is found in the mucosa. (1) The crypts in the cardiac end are shallow, while in the pyloric end the crypts frequently extend half way through the thickness of the mucosa. (2) The gastric glands are longer than the crypts in the cardiac end; toward the pyloric end the glands become shorter, tortuous, and pressed closely against the muscularis mucosa. Many of the pyloric glands are branched. (3) The parietal cells are numerous in the cardiac region and practically absent in the pyloric. The pyloric mucosa, in this way, comes to resemble that of the small intestine. In addition, an occasional villus or Brunner's gland may be found in the pyloric end."—(*Hill's Histology*.)

6. *Development of Bone*.—"The development of bone is either intramembranous or endochondral. In the latter a cartilage stage intervenes, otherwise the history in each case is the same. A synopsis of endochondral development is as follows: (1) A solid shaft of hyaline cartilage, non-vascular and without any marrow cavity. (2) In the center of this shaft the cartilage cells enlarge, their lacunæ enlarge and coalesce, particularly along lines extending toward the ends of the bone. The rosette produced by this excavation is called the primary areola of Sharpey. (3) Lime salts are deposited in the thin walls of these spaces, making calcified cartilage. (4) Osteogenetic cells and blood vessels from the periosteum enter the cartilage

spaces. The cartilage cells disappear with this invasion and the excavation, begun by the cartilage cells, is further enlarged by the bone cells. The excavated areas are now called the secondary areolæ of Sharpey, the cavities having a rich blood supply quite in contrast with the primary areolæ. The marrow cavity is excavated and the shaft becomes longitudinally porous. Endochondral bone, therefore, develops in cartilage, not from cartilage. (5) Osteogenetic cells attach themselves to the wall of these enlarged Haversian canals and become enclosed in lime deposits, forming thus the outer lamellæ and outer row of bone cells of each Haversian system. Cells with lamellæ are added centripetally to this outer row and thus ultimately complete the Haversian system, leaving a small central canal containing vessels and a nerve. Ossification begins in the center of the cartilage shaft and proceeds gradually toward each end, so that all the above changes occur at one and the same time. After birth these changes go on at the ends of the bone, so long as it keeps growing. During this period the bone is made thicker by deposits from the periosteum forming the circumferential lamellæ of bony shafts. These lamellæ are added without the intervention of a cartilage stage and therefore represent intramembranous development."—(*Hill's Histology*.)

7. A cross section of the spinal cord at the tenth dorsal vertebra will show that the outline of the cord is almost circular, with the transverse diameter a little larger than the antero-posterior; the posterior median cleft extends beyond the center of the cord; the gray matter is in considerable quantity, both horns being somewhat thick and approaching the type of the lumbar cord; there is little or none of the formative reticularis; there is no posterior paramedian groove or septum; and the central canal is nearer to the anterior than to the posterior surface of the cord.

8. Arteries and veins resemble each other, generally, in structure; they both have three coats, with the same general arrangement, but in the veins the walls are thinner in proportion to the size of the lumen of the vessel. Further, in the veins the internal coat has less elastic tissue and the endothelium cells are shorter; the middle coat has less muscle and elastic tissue and more fibrous tissue; many of the veins are provided with valves.

9. *Lymph glands* are small, bean-shaped organs, from a few millimeters to several centimeters in size. Each is surrounded by a capsule, and composed of cortex, medulla, and hilus. The capsule consists of white fibrous tissue and contains some yellow elastic and smooth muscle tissues; beneath is a lymph space exhibiting a network of reticulum and called the sinus. From the inner surface of the capsule, trabeculæ are sent into the cortex, and these divide the latter into a number of masses called secondary nodules. The lymph space continues along the trabeculæ. The cortex contains the secondary nodules and trabeculæ. The former consist of dense lymphoid tissue, and contain a germinal center. The cells are chiefly lymphocytes, which are arranged in concentric layers around the periphery. Other cells of the hyaline variety are found in the central portion. The nodules continue into the center of the node as the medullary cords. The trabeculæ separate the nodules from one another, and pass into the medulla surrounded by the lymph space. The medulla consists of the medullary cords and trabeculæ. The cords are the band-like continuations of the secondary follicles, and are separated from the trabeculæ by the lymph spaces that accompany the latter. They consist of dense lymphoid tissue, supported by reticulum. At the hilus, the medulla comes to the surface. The hilus is a scar-like depression at one side, where the vessels enter and leave. At this place, the secondary nodules are wanting, and the medulla comes to the surface."—(*Radasch's Histology*.)

BACTERIOLOGY.

1. "The *Wassermann reaction* for the diagnosis of syphilis.—If the inactivated serum from a suspected luetic is mixed with organ extract (luetic liver or guinea pig heart macerated, extracted with alcohol and inactivated) and complement (fresh guinea pig serum) added, the complement is bound if the antigen finds an homologous antibody in the serum, that is, if the serum is genuinely syphilitic. To determine whether this anchoring of the complement has taken place, the mixture, after standing for a time, is brought in contact with another mixture (of washed sheep's corpuscles and inactivated specific hemolytic serum obtained

by injecting a rabbit with sheep corpuscles), which consists of red corpuscles and their specific amboceptor. Should the complement in the first mixture not be anchored, the "hemolytic system" will be complete and hemolysis will occur. The reaction is a complicated one, and it is necessary to control it carefully. A common source of error has been the use of too large a quantity of organ extract, which has the effect of bringing about an anchoring of the complement even in the absence of the specific antibody in the serum. Noguchi has devised a modification of the Wassermann method which is simple and exceedingly delicate."—(Jordan's *Bacteriology*.)

2. *Alexins* are defensive bodies which exist normally in the blood serum.

Agglutinin is something in the blood serum of an animal affected with a bacterial disease which is capable of causing the clumping of the bacteria which cause the disease.

Precipitin is a substance in the immune blood serum which causes precipitation of an albuminous body which has been injected into the body.

3. *Diapedesis* is the passage of the blood or the red corpuscles through the unruptured walls of the blood vessels.

Phagocytosis is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria. Hence it is a protective process, and has been claimed to be an essential process in immunity.

4. *Staphylococcus* is stained with aqueous solutions of the anilin dyes, and also by Gram's method.

Streptococcus is stained with aqueous solutions of the anilin dyes, and also by Gram's method.

Negri bodies are stained by methylene blue and eosin, also by Giemsa's method.

5. The diphtheria bacillus grows readily upon all the ordinary media, and is very easy to obtain in pure culture, plates not being necessary. Material from the infected throat can be taken with a swab or platinum loop and spread upon the surface of several successive tubes of Loeffler's blood serum media (which consists of three parts of blood serum with one part of ordinary bouillon to which has been added one per cent. of glucose).

6. *Toxins* are poisonous products of bacteria or of ptomaines or leucomaines.

Endotoxins are toxins which are not secreted into the culture medium by the bacteria, but are rather attached to the bodies of the bacteria.

Autotoxins are toxins which originate within the body upon which they act.

7. The *pneumococcus* (cf Friedlander) is an encapsulated bacillus of variable length, non-motile, non-flagellated, aerobic and optionally anaerobic, non-liquefying, and pathogenic; it stains with the ordinary anilin dyes, but does not retain the color when stained by Gram's method. Its form is so variable that it has been described by different writers as a coccus or a bacterium.

The *parasite of tertian malarial fever* is about one and a half times the diameter of a red corpuscle, and is mulberry shaped; by the process of segmentation, from 12 to 24 young parasites are formed; the male gametocyte is smaller than the female gametocyte; there are no crescents.

8. The *Widal test for typhoid fever* "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology*.)

Von Pirquet's method of cutaneous diagnosis of tuberculosis.—"Two small drops of old tuberculin are placed on the skin of the front of the forearm, about

2 inches apart, and the skin is slightly scarified, first at a point midway between them, and then through each of the drops. A convenient scarifier is a piece of heavy platinum wire, the end of which is hammered to a chisel edge. This is held at right angles to the skin, and rotated six to twelve times with just sufficient pressure to remove the epidermis without drawing blood. In about ten minutes the excess of tuberculin is gently wiped away with cotton. No bandage is necessary. A positive reaction is shown by the appearance in twenty-four to forty-eight hours of a papule with red areola, which contrasts markedly with the small red spot left by the control scarification."—(Todd's *Clinical Diagnosis*.)

9. The *Staphylococcus pyogenes aureus* and the *Streptococcus pyogenes* are the pus-producing organisms which cause the greatest mortality. The *Staphylococcus pyogenes aureus* may be found in boils, carbuncles, abscesses, endocarditis, various skin lesions, diseases of lungs, spleen, and kidneys, osteomyelitis. The *Streptococcus pyogenes* may be found in erysipelas, endocarditis, meningitis, periostitis, otitis, emphysema, pneumonia, lymphangitis, sepsis, puerperal endometritis, scarlet fever.

10. *Flagellated bacteria* are bacteria which have flagella or long filaments or hair-like structures, which are undulating and may cause the motility of the bacteria to which they are attached. *Flagellated pathogenic organisms*: *Bacillus pyocyaneus*, *Bacillus tetani*, *Spirillum cholerae Asiaticæ*, *Bacillus typhosus*, *Bacillus coli communis*, *Bacillus enteritidis*, *Bacillus dysenteriae*, *Bacillus icteroides*, *Bacillus oedematis maligni*, *Bacillus anthracis symptomatici*.

OBSTETRICS.

1. *Puerperal septicemia* is septic intoxication with the presence of living pyogenic bacteria in the blood occurring during the puerperium. *Symptoms*: Chill; rapid rise in temperature, to about 103° or 104°, higher in the evening than in the morning; sweats; rapid pulse; depression; dry tongue; anorexia; carphologia; scanty, high-colored, albuminous urine; restlessness; sometimes delirium or coma. The uterus is large, and tender; the lochia are diminished or suppressed; the milk secretion is often suppressed; pain in the abdomen; peritonitis may develop. *Treatment*: Prophylaxis is of the greatest importance. Purgatives; vaginal douches; some recommend curettage, others decry it; the introduction of antiseptics into the uterus; supportive and general treatment are indicated; specific sera and vaccines have been recommended by some.

2. The uterus is supplied by the uterine and ovarian arteries; the veins correspond to the arteries.

3. *Changes that take place in the circulatory apparatus at birth*: The hypogastric arteries dwindle and become impervious; the Eustachian valve atrophies; the foramen ovale closes; the ductus arteriosus and ductus venosus become obliterated; the umbilical vein becomes obliterated and is afterward known as the round ligament of the liver.

4. *Pregnancy*: The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroma: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

5. *Indications for the use of forceps* are: (1) *Forces at fault*: Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (a) Impending exhaustion; (b) arrest of head, from feeble pains. (2) *Passages at fault*: Moderate narrowing, 3¼ to 3½ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault*: A. Dystocia due to (a) occipito-posterior, (b) mento-anterior face, (c) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications*: Hemorrhage; prolapsed funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both (Jewett). *Conditions necessary for the use of forceps* are: (1) The rectum and bladder must be

empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

Cesarean section (conservative). "Indications: The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the 'positive' indication for cesarean section; there is nothing else to be done. Flat pelvis having a conjugata vera of $2\frac{1}{4}$ inches or less, and justo-minor pelvis with a conjugata vera of $2\frac{1}{2}$ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible, but cesarean section is agreed upon to save the life of the child; (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a living child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by post-mortem cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements, may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication."—King's *Obstetrics*.)

6. By the *hygiene of pregnancy* is meant the care which should be observed by the pregnant woman for the preservation of health and strength both of herself and of the fetus. The pregnant woman should take moderate exercise in the open air; in the last month massage may take the place of exercise. Daily bathing in tepid water, care of the teeth, regularity of the bowels, ample sleep in a well-ventilated room, plenty (but not too much) of simple, nourishing and easily digested food, at regular hours, clothing not too tight, especially about the abdomen and breasts; attention to the nipples, regular examination of the urine, and the restriction of marital relations are the main points to which advice should be directed.

7. Three diseases to which pregnancy may predispose: Pernicious vomiting, eclampsia, varicose veins. *Symptoms of eclampsia*: Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions.—(King.)

8. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatiform mole; (7) habitually large fetal head.

Method of performing premature labor: "Catheterization of the uterus: The first step consists in separation of the membranes from the lower uterine segment by means of a uterine sound or with the finger. The operation must be aseptic. Detachment of the membranes with the sound may be done with the woman in either the left lateral or dorsal recumbent position. For the use of the hand the dorsal position is best. The second step consists in the insertion of one or more No. 12 English bougies, or a sterile rectal tube, between the membranes and the uterus. No anesthetic is required. Usually the bougie or rectal tube is most read-

ily passed with the aid of the Sims position, the Sims speculum exposing the cervix, which is drawn forward and held with a volsella. The bougie is sterilized by boiling or steaming, the proximal end is cut off, and a stylet inserted. To facilitate introduction the bougie is bent to nearly a right angle at about three inches from the distal end, giving it a large curve. Great care must be used to avoid rupturing the membranes. The instrument is then pushed up gently and in the direction in which it passes most easily. After it has entered between the membranes and the uterine wall, the stylet is drawn down about one inch. The flexible tip of the bougie finds its way readily with little risk of perforating the membranes. The bougie fully in place, the stylet is withdrawn. A second bougie may be inserted if it can be pushed into place without too much difficulty. Bleeding is probable evidence that the instrument has passed behind the placenta. The hemorrhage may occasionally be excessive. It is then best to withdraw the instrument and pass it in another direction. A light tampon of gauze may be packed in the vagina, but it is not required to support the bougie. The instrument is left to be expelled with the child. Labor usually is established within twenty-four hours. This method is not suited to cases in which immediate delivery is called for."—(Polak's *Obstetrics*.)

9. *OPHTHALMIA NEONATORUM*. *Prophylaxis*: Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment*: Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

10. *Abortion* is expulsion or delivery of the fetus before it is viable, that is up to about the twenty-eighth week. *Premature labor* is expulsion or delivery of the fetus between the twenty-eighth week and term.

GYNECOLOGY.

1. A complete gynecological examination would include (1) anamnesis, including family history; personal history, with special reference to menstruation, labors, and miscarriages, and present illness. (2) Examination of the abdomen (and breasts), including inspection, palpation, percussion, auscultation, and mensuration. (3) Inspection of the external genitals. (4) Vaginal examination, digital, bimanual, and with speculum. (5) Bimanual examination of uterus and appendages. (6) Sometimes the sound, or curette, may be required. (7) Chemical and microscopical examination of the urine. (8) Microscopical examination of discharges or uterine scrapings. (9) Rectal examination. (10) Cystoscopic examination and perhaps ureteral catheterization. (11) In case of phantom tumor or pseudocystitis, anesthetization would be required.

2. *Pfannenstiel's incision* avoids a median incision, the transverse scar is partly hidden by the pubic hair, hernia is said to be less liable to follow. The disadvantage is that it is only available for limited operations on the tubes, ovaries, uterus, bladder, and pelvic cavity.

METORRHAGIA: *Causes*: Salpingitis, ovaritis, ovarian tumors, endometritis, endocervicitis, metritis; fibroids, sarcoma, carcinoma or polyps of uterus; prolapsed, retroflexed, or retroverted uterus; subinvolution; and general diseases (such as scorbutus, purpura, hemophilia, acute fevers, nephritis, hepatic cirrhosis).

3. *Perineorrhapy*: "The labia are seized with Allis' forceps at the level of the lowest caruncula myrtiformes. A guide stitch is placed in the posterior vaginal wall directly under the external urinary meatus. By pulling one Allis forceps and the guide stitch in opposite directions outward and downward, the posterior sulcus is exposed; denudation is required, even in a recent tear, for a part of it is always submucous. The other sulcus is exposed and denuded. Then by holding the guide stitch upward in the middle line and pulling the forceps apart the mucous membrane between the sulci is denuded or freshly torn surfaces covered with granulation-tissue are scraped with the edge of a knife. The ruptured levator ani muscle in the posterior sulci is united with a double tier suture of chromic gut, two half hitches being taken in the stitch as it turns upward after coming down from the

apex of the wound, in its deeper portion to the base. One knot at the apex of the sulcal denudation secures the stitch. The retracted ends of the transversus perinei and bulbocavernosus muscles are brought together by silk-worm sutures. Finally, a single stitch at the top of the perineal wound unites the posterior commissure of the vulva, restoring the fossa navicularis. The perineal stitches are knotted; they are removed on the twelfth day."—(Hirst's *Obstetrics*.)

4. *Vaginal examination of a virgin* should not be undertaken unless absolutely necessary, an anesthetic should be employed if possible, and only one finger should be used.

5. Ectopic gestation, and ovarian cyst, with twisted pedicle.

6. *Ventrofixation and ventrosuspension*: Hermann (Students' *Handbook of Gynecology*) states objections to this operation as follows: "(1) Its risk. Oversights will occur in the practice even of the most careful; but the risk is very small. (2) Adhesions within the peritoneum are sometimes absorbed. They are absorbed often enough to make stitching of peritoneum to peritoneum unsatisfactory. After abdominal section ventral hernia may first develop after the scar has held firm for twelve years; and possibly the new attachment of the uterus may also, after many years, give way. (3) The operation lifts up the uterus. If the vulval orifice is very large there may still be a protrusion of the vaginal mucous membrane. It is well, therefore, to precede ventral fixation in women past child bearing by posterior colporrhaphy. (4) It is said to cause difficulty in labor, should the patient become pregnant. It does not always do so; and in many cases reported as illustrating such difficulty, the ventral fixation was not the cause of the difficulty. Ventral fixation after colporrhaphy, if the result be permanent, relieves the patient of any necessity for the continual readjustment of a pessary, and lifts the uterus up effectually. Ventral fixation is not advised in cases in which the womb can be comfortably kept up by a pessary."

7. "The indications for oophorectomy are chiefly infections of the ovaries; inflammations and their consequences; certain rare and otherwise incurable cases of dysmenorrhea; certain otherwise incurable cases of ovarian pain, independent of the periods, and making the patient an incurable invalid; clear cases of menstrual epilepsy; menstrual insanity, when the attacks occur only during the menstrual week, the patient being free from them during the interval; osteomalacia; and bleeding uterine fibromata, of small size, where the patient declines hysterectomy and other means fail."—(Reed's *Gynecology*.)

8. The perineum should be repaired; and colporrhaphy (anterior and posterior) be done for the cystocele and rectocele; ventrosuspension or ventrofixation may be done for the procidentia, though this last procedure is not as imperative in the case of a woman of 50 years of age as it would be in a much younger woman.

9. *Contraindications to uterine curettage*: The least suspicion of even the possibility of pregnancy; menstruation; acute endometritis; malignant disease of the uterus or vagina; acute pelvic inflammation.

10. If there is nothing the matter with the appendix, there can be no necessity for its removal; but some surgeons believe that in case of any abdominal operation it is well to remove the appendix in order that it may not cause trouble later on. It may be well, before an abdominal operation, to consult the wishes of the patient as to the removal of a healthy organ.

(To be concluded.)

On the Occurrence of Tubercle Bacilli in the Blood of Patients with Pulmonary Tuberculosis.—Lawrason Brown, F. H. Heise, and S. A. Petroff investigated this subject in 84 patients. The blood of the latter was inoculated into guinea pigs and positive results were obtained only in three cases (3.5 per cent.). Two of these cases were far advanced and one was moderately advanced but not active and had not reacted to large doses of tuberculin. Of 63 cases that had not received any tuberculin two (3.17 per cent.) gave a positive result. Of 21 cases that had received one milligram or more of tuberculin, one (4.8 per cent.) gave a positive result. The conclusion is drawn that tubercle bacilli are not often found in the blood of patients with pulmonary tuberculosis. Tuberculin even in large doses has no influence in causing the passage of tubercle bacilli into the blood stream. *Zeitschrift für Tuberkulose*.

Miscellany.

Diphtheria Morbidity.—The Weekly Bulletin of the New York City Department of Health recently announced the results of a conference held at the department to discuss more effective control of the infectious diseases of childhood. It was generally agreed that the prevalence of diphtheria was now as great, as, or even greater than, it was years ago, although the mortality from the disease has been greatly reduced; that is, although the efforts of the health authorities in providing facilities for early diagnosis and making antitoxin treatment available, have produced a marked decrease in the number of deaths, they have had no influence on the number of cases occurring. This is due to the large number of "carriers" of diphtheria bacilli. The work thus far done in active immunization with toxin-antitoxin mixtures has been very encouraging, and the suggestion was made that this be introduced as a regular procedure in the control of diphtheria. Passive immunization will, of course, be continued as a preventive of the direct infection of susceptible individuals in a family where a case of diphtheria has occurred, but this form of immunization is of short duration, and where a more lasting protection is desired active immunization should be employed. Investigations at the Willard Parker Hospital have shown that the department's present procedure of permitting the termination of a case of diphtheria after two negative cultures have been obtained is open to criticism, since a third culture after two negative ones has shown bacilli in about 20 per cent. of the cases. It was suggested, therefore, that all cases of diphtheria be held for at least ten days and then discharged only after two negative cultures have been obtained, and that unless repeated cultures are made from the throats of other members of the family they should be quarantined for from ten to twelve days. The establishment of such a period will in itself offer some security as to the absence of diphtheria in a fair proportion of cases.

An Efficient Disinfectant.—Albert F. Stevenson, sanitary chemist, hygienic laboratory, U. S. Public Health Service, recommends the following as an efficient disinfectant for household or public use: Pine oil 1,000 (35.3 ounces by weight); rosin, 400 (14.2 ounces); 25 per cent. solution of sodium hydroxide, 200 (7.1 ounces). This will make approximately 1,500 c.c. or 1.6 quarts of disinfectant. The pine oil and rosin are heated together in a covered enameled ware pail until the rosin is all dissolved. The mixture is cooled to 80° C., the sodium hydroxide solution added, and the liquid violently stirred or beaten for at least 10 minutes with a rotary egg beater. Sufficient water is added to make mixture to the original weight. The preparation is then cooled quickly by placing the pail in cold water. It is stored in glass or metal containers till used. This disinfectant may be used wherever the ordinary coal-tar compounds are used. It has a much more pleasing odor than the coal-tar compounds, and can be used where these products, on account of their odor, are not practical. It will not attack fabrics or metals and is recommended for the disinfection of all articles used in the care of contagious diseases. It has not a displeasing taste, and has been used with success as an antiseptic throat spray and tooth and mouth wash. It can be used in any dilution up to 1:500. It has a hygienic laboratory phenol coefficient of between 4 and 6.—*Public Health Reports*.

RADIUM.

ITS PHYSIOCHEMICAL PROPERTIES CONSIDERED WITH RELATION TO HIGH BLOOD PRESSURE.*

BY C. EVERETT FIELD, M.D.,

NEW YORK.

THE onward march of arteriosclerosis has never been offset to any material extent by the few flank dietetic attacks made against it. High blood pressure to-day, more than ever before, is engaging the attention of the medical profession, with no small degree of anxiety. After the early prime of life, say forty-five years, cardiovascular degeneration directly or indirectly causes, by long odds, the largest quota of deaths. Furthermore, each decade during the past fifty years shows this condition enormously increasing. These morbid processes are, to a greater and greater degree, becoming prevalent among men and women of position and influence, until we are face to face with a most vital problem. The far-reaching results of hypertension, as witnessed by the diagnostician and clinician, are now being coped with by our great life insurance bodies and even the general public is recognizing in no small way the seriousness of this evil that makes its appearance so insidiously. We all too frequently meet a well-advanced degenerative change in the cardiovascular system of men who have never known a day of illness, and to the eye are as pictures of health.

Hypertension¹ in periods long or short, precedes degenerative processes and at times gives little warning, owing to the promptness with which some form of compensation takes place. We may also conclude that hypertension from any cause cannot persist for any considerable period, without developing organic changes in the heart, kidney, and general vascular system. The importance of recognizing more clearly the underlying features of etiology upon which to build rational treatment is magnified as we review the great and increasing army of the subjects of arteriosclerosis, myocardial degeneration, and nephritis that are ever passing. That we can, by diet and hygiene, relieve or delay the inevitable does not suffice, for it remains that daily in the United States alone, we have a death rate of some 2500 traceable to cardiovascular degenerative processes, kidney lesions, etc. All too commonly do we see in evidence, as stated by Dr. Fisk² of the Life Extension Institute, "The human clock breaking down instead of running down."

In a paper of this type we cannot devote much space to general etiology, except to refer to those predisposing and direct causes, such as overwork,

*Read by invitation before the Washington Heights Medical Society, at New York, November 23, 1915.

loss of sleep, nerve strain, faulty digestion, and toxic principles. Romberg is quoted as saying, "Everyone acquires his arteriosclerosis within the circuit which he has taxed most." Metabolism is the keystone of hypertension. Finding all channels leading to the exhibition of toxic influence, we naturally cast our hope for a lifting of the veil to the biochemist. We have gained considerable knowledge as relates to the body chemistry of this subject by our study of diet.³ We are familiar with the toxins developed by the ingestion of certain foods; yet Klemperer tells us "Although an excess of animal protein in the diet is believed to be one cause of high blood pressure there is really no proof that a meat diet can cause arteriosclerosis." Fundamentally, all such data revert to the fact that the metabolic processes causing hypertensions are solely disturbed fermentation and due to toxic principles.

Our present understanding of high blood pressure is being met in treatment methods of the dingy past. Measures of prophylactic, symptomatic, and curative treatment are practised. Under prophylaxis we arrange a non-nitrogenous diet of limited amount, provide baths, massage, administer the high-frequency current, change the habits of the patient, etc. Our symptomatic treatment, usually, in the dangerous case consists of bleeding. We advise calomel or oil, as a brisk purge by direct removal of the fluids reduces tension; also toxemia is lessened. When there is decomposition of food products *Bacillus bulgaricus* produces results. In like manner we have the nitrites and digitalis broadly used; but of these Le Fevre has cautioned: "In the treatment of cardiac and renal diseases the greatest danger next to the abuse of digitalis is the unjustifiable administration of the nitrites." This warning is given because of the fact that the latter is transient in effect and at times increases the irritability of the cardiovascular system. With curative treatment largely limited to a few cases of gout, syphilis, and alcoholism, we must seek further if we hope to evolve curative measures for the greater group, probably 90 per cent., where the underlying causes are metabolic. In other words, we must still depend upon suitable diet or find some other means that shall serve to *normalize* those body ferments to the point where a more liberal diet can be encouraged. As history records to-day, the great majority of high blood pressure cases run their course—sooner or later compensation is called in,⁴ the hypertrophied heart will become insufficient and we have a train of symptoms such as dyspnea, precordial distress, edema, and death if cerebral rupture does not more hastily break in on the program.

Recognizing, then, fully the status of the body ferments, and the fact that each acts in harmony with constituents of its own substance, we can

readily see how complex must be a study of the multitude of ferments which in the body combine to build up all that is vital and consume that which is waste. Administering drugs with the hope of influencing metabolism, we can appreciate, utterly fails because of the fact that what might activate one ferment would at the same time throw out of balance another. The biochemist is bringing to us great truths that are resulting in revolutionary advances in medicine, and the application of physical chemistry is the theme of the moment. Dr. Sailer^o of Philadelphia, a few days since, said: "The fundamental element in physics, in chemistry, possibly in the universe, was the atom, and until a clear idea of the structure of the atom was had, much progress in the solution of the problems under consideration could not be made." The close interrelation of ionization and colloidal states is vital in our study of every phase of the high blood pressure subject. The phenomena of ionization as evidenced in many of the normal ferment processes may be illustrated in its importance by a definition: "The modification of a substance by which it acquires electrical charges is termed ionization; for instance, common salt and sugar in water, designated formerly as a solution. We now know that the activity of the salt is materially increased while the sugar suffers no change—the sodium atoms acquiring a positive electrical charge and the chlorine atoms a negative charge." The above thought by Leffman^o is here introduced with the hope of paralleling the action of radioactivity in activating chemical processes, and at the same time to give appreciation of his work.

According to von Noorden,⁷ radioactive elements exert forces which, in accord with the definite laws of physics, markedly influence biologic processes. Furthermore, the chemicophysical properties of radium may be traced in the human body even in the minutest doses. Metabolism, while classed as a body chemistry, is in itself dependent to no small extent on physics. In the laboratory radium readily activates and intensifies fermentative and digestive processes; within the body, it stimulates even more actively the numerous ferments. The efficiency of radium in catalysis and autolysis⁸ will be better understood if in a moment we review a few of the commonly well-known facts as regards this element.

Radioactive substances present three distinct products of disintegration which we term rays. Alpha rays are positively charged helium atoms and constitute 90 per cent. of the energy of radium. Beta rays, also electrons, in turn are negatively charged particles. Gamma rays are not material in nature, being classified as exceedingly short-length waves of ultra violet light. In the process of decay or transmutation, something happens within the tiny atom of radium, and much as the meteor flies from the planet, the alpha ray is spontaneously thrown off into space with a speed of over 12,000 miles per second. From this another and still another particle is born until the entire series in evolution is complete. In common with the liberation of the alpha particle, we have the formation of a gaseous substance known as emanation, which contains in itself all of the power and energy of radium. The radiations of emanation acting as carriers of enormous energy within the body develop heat and electricity and foster chemical transformation. By its use we permeate the body with a stream of electrons

through the channel of the blood stream. It carries a *normalizing* activity to the tissues, fluids, protoplasm, cells, and nuclei. Therapy with radioactive substances may be designated as the administration of *fluid electricity*. This is probably the most clear description we could give of its physical force and purpose.

Abundant literature detailing the exhaustive biological and physiological research of worthy observers is at hand and can be accepted, especially that which pertains to metabolism. The careful and accurate findings of such workers as von Noorden, Gudzent, His, Deutelmöser, Klemperer, Falta, and von Neusser tend to substantiate much of the true physiological effects of emanation. The physiological manifestations of radium naturally center around its effect on metabolism and the blood. There are evidences of a selective influence as regards radium, such as the affinity that attracts it to the bone marrow, where it serves to increase markedly the red blood count. There is temporary leucocytosis. It is said to aid in keeping uric acid in a soluble form and to promote the elimination of that already deposited. Dilatation of the blood vessels follows an excitation of the vasomotor nerves; the viscosity of the blood is diminished. Digestive processes are greatly improved by activating the ferments. Diuresis is produced. Emanation exerts stimulant, tonic, and sedative influences. Following its use respiration is improved.

As we come to a deeper study of the biochemical processes we will secure knowledge which, I am constrained to believe, will be as revolutionary to some of our therapeutics as was the exploding of the time-honored atomic theory. The researches of Gudzent and Löwenthal in purin metabolism found it activated by the smallest doses of radioactive waters. Carbohydrates are mobilized and oxidized in increased quantities. Bickell and Bergell have proven the activation by emanation of peptic ferments in the stomach. Braunstein, Richet, and Deutelmöser also have reported as to the activities of glycolytic, urolytic, pancreatic, and lactic-acid ferments. Neuberg has given valuable data on autolytic fermentation. That radium increases protein metabolism indicates its use in gout and old age conditions. There remains a mass of work already reported as to metabolic activation with radium which we cannot even here mention; we, however, must let these brief references be left as indicative, and hasten on to the more recent work with radium therapy that bears directly on our subject.

To have the radium situation clearly before our minds, we must acknowledge that much of the early experimental research with radium had many of the hindrances common to the study of so rare and new an element. The theories relating to the causative features of high blood pressure are many; but for our immediate need we care not to debate now whether it is due to a hyperplasia of the suprarenal capsule or, according to the old theories of Cohnheim and Traube, to mechanical interference in the flow of the blood stream, for we may content ourselves in the belief as clinicians that faulty ferments of toxic origin are the basic factors.

From the earliest experiments to the present, lowering of high blood pressure during radium treatments has been the common report. Physiochemical processes are exact and the physiological and biological manifestations that follow must to a similar degree, be definite. Therefore it is that,

in almost 95 per cent. of the high blood pressure cases treated, certain improvements are promptly noted, precordial distress, headache, vertigo, disappear at times even with small dosage. The general energy of the heart is markedly improved, and peripheral resistance is reduced. A factor that by some has been discounted is the viscosity of the blood; yet a change in type exerts an enormous influence of the arterial system—under emanation it is rendered less viscid. The elasticity of the muscular wall of the artery relieves the heart of much unnecessary load. When the tonicity is low, increased tension results. Radium emanation improves the general muscle tone of the entire system. All these processes naturally are the outcome of the influence of radium on the various ferments that may be disordered.

I am frequently asked the question, "Just what can we hope for clinically?" Recognized early, metabolic processes may be promptly improved, with the hope of a permanent cure. We have a right to assume that the process of hypertension can be checked so as to prevent the development of a nephritis. Indeed, I feel that there is a reason to believe that Bright's disease as a symptom may be wiped out. When nephritis and cardiac lesions are advanced, the pathological processes can surely be held in check and life in a measure conserved; while at the last stake with a broken compensation we may sustain the patient by lowering tension, building up resistance, increasing somewhat the elasticity of the blood vessels, thereby lessening the danger of their rupture and materially adding to the comfort of the patient.

Administration.—Radium may be administered by means of emanation inhalation, radioactive waters for drinking, solutions of radium salts for drinking, by means of emanation baths, or by intravenous or subcutaneous administration of radium bromide or radium chloride. Wherever dosage in micrograms of radium salts is quoted it refers to *radium element*. Radium has absolutely no toxic effects, it being accepted as harmoniously by the human system as is sunlight by the plant. The classification of clinical and dosage data reported by Rowntree and Baetjer⁹ is of considerable worth. Dosage in radioactive or emanation water is being used in variation of from 1000 to 1,000,000 Mache units, and the pure radium element in the form of radium chloride has been administered intravenously in dosage as high as 1000 micrograms or the equivalent of 2,700,000 Mache units in one dose without any untoward effects. With radioactive waters, von Noorden found but little results until his dosage of water approximated 20,000 Mache units daily. The usual dose of radioactive or emanation water used by the London Radium Institute¹⁰ gives a minimum of 250,000 Mache units daily and a maximum of 1,000,000 Mache units. Proescher¹¹ and Cameron have made over 2000 intravenous injections of radium chloride in doses averaging 50 micrograms, and my personal observations cover the administration of over 800 similar treatments, and I find no report of any unpleasant effects. That radium is not permanently deposited, and that it is finally eliminated from the system is well covered in a research by Seil, Viol, and Gordon,¹² who showed the character of complete elimination and its duration in the human. Most interesting research is now being done in measuring the radioactive content of the blood for weeks following treatment. The activity of radio-

active waters is of short duration and consequently they are limited in their application. It is probable that no emanation can be traced two hours after taking, whereas radium solution by mouth can be traced and measured up to the sixth day. Following an intravenous injection of radium chloride it can be traced in the blood at least twelve weeks thereafter. Subcutaneous application of the radium by injection reduces its dosage effect about one-half. Some of the earliest of injections of radium element were made by Brill, Falta, Freund, Zehner, and von Noorden. The latter reported no disturbing effects and urged larger doses and deeper study.

So far as dosage is concerned in high blood pressure we are largely governed by the chronicity of the case and the involvement. Personally, I feel my best results have been shown in what we would term low dosage. Delano¹³ of Boston has checked up some exceedingly important findings derived with low dosage. He has found his average does to be 4 micrograms daily. It is my usual plan to give an injection of one 25-microgram (radium chloride) ampulle (2 c.c. normal saline solution), and following with a solution of distilled water, 2 oz., containing 2 micrograms of radium chloride given by mouth as one dose three times a week. After four weeks this drinking solution is cut to two doses per week. While the results are prompt, I never accept a case for less than twelve to sixteen weeks' treatment and observation. Careful histories of the laboratory findings are always to be made. The patient may or may not be placed on diet and other rules of hygiene as may seem indicated. In private cases I would of course observe the above, in others I have preferred to watch the results without special or rigid diet. Under such a treatment we have a right to expect by far the large majority of cases of systolic pressures (running from 160 mm. to 200 mm.) to be influenced to drop from 15 mm. to 40 mm. As a rule, active symptoms such as precordial distress, vertigo, and headache disappear in many cases within a few days.

Where radium solutions per os alone are given, my dosage starts at 6 micrograms per day in three doses; this to continue for four weeks as a rule, then to follow at 6 micrograms per week for the balance of the course. This plan of treatment does not give as uniformly good results as a course inaugurated with an intravenous injection. The plan of insisting on the long time treatment was arrived at, owing to the fact that after the initial drop in pressure, or within five days, the patients generally felt so much improved that there was a tendency to discontinue treatment. It was necessary to make it clear that the early relief had nothing to do with the permanency of the effect most to be desired. In dealing with a disordered metabolism of long standing it would be unwise even to assume that radium would accomplish the impossible. Patience and real radium with or without a portion of psychology are necessary factors to the successful administration of those cases. In your mind will naturally arise the question, what of the permanency of such treatment. To this I can reply that fully three-fourths of the cases have held without further treatment for from six to twelve months. There are many of the early cases treated nearly two years ago that have suffered no material rise. Others where pressure has gone up sufficient to produce symptoms have been quickly touched up

with a two or three weeks' treatment. Some of these returned with their trouble on account of growing bold with their diet. An interesting feature in a large number of my cases has been an activation of sexual powers. Insomnia and nervous symptoms are improved and the patients invariably take on a feeling of well being.

Compensatory functions can be sustained and greatly improved at times with extremely low dosage of radium. In such cases we may observe both systolic and diastolic pressures slowly coming down in a fairly even proportion. Although I can find no record of any unfavorable action following the administration of the soluble salts of radium, I would naturally urge caution in attempting sudden reductions in compensatory high pressures. Here must come a full understanding as to the type of compensation. For the purpose of this paper I have intentionally refrained from dealing with compensatory cases and my selection has been in a measure confined to those types showing relatively a high systolic and a low diastolic pressure. In a series of 135 cases classified, the average systolic pressure was 190 and the average reduction showed at 40 mm.

The following case histories, selected from the group, although reported with limited detail, I trust will serve to illustrate everyday types with results that should be indicative. Almost all of these cases had received general treatment for a greater or lesser period and were classed as well advanced. In the entire series there were but eight cases that failed to respond and three of these were single-treatment patients. Several of the cases herein reported are one-treatment types. Such a method, without follow-up dosage, is not advised, but the final results are none the less interesting.

There is an opportunity of vast importance here waiting for the real research worker to pick up the thread and trace the terminal activities and results as they may relate to the physiochemical properties of radium in catalysis and autolysis. Beyond giving treatment to the active case, we are now called upon to give attention to those measures of prevention which will enable those advancing to the fifth and sixth decade to grow old gracefully.

CASE I.—Mrs. R. H., aet. 67. Previous history one of health. Called for treatment following prolonged spell of vertigo—thought by family to be a slight stroke—pressure 220 mm. Had complained of distress around heart. No compensatory influences. Brisk cathartic followed by 50 mcgm. radium intravenously. Twenty-four hours later pressure 180 mm. Four days later back to 200 mm. A second injection of 50 mcgm. given on tenth day reduced pressure to 175 mm. Under the influence of 6 mcgm. per week in divided doses for eight weeks pressure fluctuated between 160 mm. and 170 mm. It is interesting to note that the patient's waist measurement after ten weeks had reduced seven inches.

CASE II.—Mr. P. R., broker, aet. 58. Suffered from trifacial neuralgia for eighteen months. Had received all treatments including injections of alcohol in the nerve sheath. Pressure 175 mm. Limited arteriosclerosis, nervous, loss of memory, exceedingly poor digestion, excessive intestinal fermentation. Two injections five days apart of 50 mcgm. each were given. Final pressure taken four weeks after first injection showed 140 mm. Pain subsided to the point of almost entire freedom. However, during the eighteen months that have passed at times there is a slight tinge of pain that reminds him that there is still some small influence at work.

CASE III.—Mrs. L. M., aet. 50. History of chronic nephritis of ten years' standing. Cardiac hypertrophy. Blood pressure 200 mm. Marked edema of lower extremities, shortness of breath. Had been on rigid diet for five years. Headaches constant. Rheumatoid pains and some arteriosclerosis. This patient was treated

with radium solutions, for drinking only, on a dosage of 2 mcgm. t.i.d. for ten days, then 2 mcgm. per day for two weeks. But little influence was shown on the pressure for nearly three weeks, although the patient's breathing was much improved and the edema was less. Increased her exercise. Treatment was carried on for ten weeks longer on a dosage of 6 mcgm. weekly and then discontinued. Gradual decrease in pressure to 170 mm. Six months have elapsed and patient has had no disturbing symptoms.

CASE IV.—Mrs. M., aet. 60. Pressure 180 mm. Consulted for arteriosclerosis in early stage. Characteristic symptoms. Had had operation for gall-bladder trouble. Years of gastrointestinal fermentation. Radium solution only advised. In five weeks took 102 mcgm. of radium chloride. Discontinued on account of marked general improvement in vitality. Digestive processes improved.

CASE V.—Mr. T. S., literary man, aet. 67. Pressure 165 mm. Evidence of early arteriosclerosis, insomnia, precordial distress, with evidences of cardiac load; exhaustion on slight effort. On request was placed on radioactive waters in dosage of about 15,000 Mache units daily. After three weeks reported with great improvement. Complexion clear, eyes bright, ready for exercise and remarked that he did not know he had a heart. Pressure reduction about 15 mm.

CASE VI.—Mrs. E. B., aet. 61.—Had suffered from neurasthenia more or less for eight years. Had been treated for "nervous heart." Commonly complained of much gas formation after eating. Pressure 170 mm. Pulse 90. Heart slightly hypertrophied. Complained of smothering sensation over heart. Rheumatic tendency with a borderline on gout. Intravenous treatment could not be given. Under administration of 28 mcgm. per week in form of drinking solution most of the troublesome symptoms disappeared, but up to the fifth week, when all treatment was discontinued, there was practically no change in the blood pressure.

CASE VII.—Mrs. E., aet. 67. Rheumatoid arthritis. Case of advanced stage. Pressure of 175 mm. Arteriosclerosis advanced with all active symptoms, most trouble asthmatic tendency, on rigid diet. Had received treatment at all the noted spas with only temporary relief. Compensation poorly officiating. Radium solutions in low dosage by mouth relieved respiratory symptoms and improved precordial distress to some degree. On advancing the dose to 6 mcgm. daily, after ten days' reaction in the rheumatoid processes presented. This pain seemed to activate her other troubles. All treatment discontinued for ten days. Treatment renewed on small dosage of 2 mcgm. daily and again relief was obtained. No action whatever on the blood pressure could be observed.

CASE VIII.—Mr. J. M., broker, aet. 62. Systolic pressure 180 mm. under observation and treatment fifteen months previously. Case presents symptoms of vertigo, precordial distress, insomnia, etc. Gastrointestinal fermentation prominent. Recently developed nephritis. Administered by intravenous method 50 mcgm. radium chloride July 12. Pressure July 14, 150 mm. Improved respiration noted. July 18, 25 mcgm. radium chloride intravenously, followed three times weekly with 2 mcgm. radium chloride in distilled water per os. September 2, systolic 140 mm. All physical symptoms relieved. Urine showed no albumin or casts. October 10, patient discharged, pressure 150 mm.

CASE IX.—Mrs. D., aet. 57. Pressure 210 mm. General arteriosclerosis with all symptoms. Had been a very active woman; had to cease all occupation for the last eight months. General treatment influenced the hypertension only temporarily and gave little improvement in symptoms. One injection of 50 mcgm. given intravenously; pressure came down 30 mm. during the next twenty-four hours. At the end of three weeks, pressure had settled at 188 mm. and all symptoms had disappeared. General health very good and could do all work she used to do ten years ago. Reports a year after the injection that she is in fine shape. Pressure 185 mm.

CASE X.—Professor, aet. 50. Violent headaches for the last six years. Had to stop his lectures frequently. All functions disturbed, specially digestion. Wassermann negative. Arteriosclerosis with blood pressure of 230 mm. General intestinal fermentation. No other known cause. One injection of 50 mcgm. radium element given at 12 noon. Pressure down to 200 mm. at 6 P. M. Four weeks after injection patient has pressure of 176 mm. and says that he never felt better; has the sensation of having much smaller weight of body.

Attends to daily work regularly and a year after the injection is in very good health.

CASE XI.—R., butcher. Consulted for general malaise, headache, vertigo, etc. Blood pressure 200 mm. One injection of 50 mcgm. reduced the pressure to 180 mm. in seven hours. Had 165 mm. at the end of three weeks. Varies from 160 mm. to 165 mm. at the end of eighteen months. Patient in very good health.

CASE XII.—Mr. W., aet. 72. Suffering from trifacial neuralgia for the last eleven years. General health fairly good. Blood pressure 220 mm. One 50 mcgm. ampulle injected at 3 P.M. Next morning pressure was 180 mm.; three weeks after the injection shows 175 mm. to 180 mm. and stayed at this mark since that time (a year and a half). Most surprisingly, the neuralgia disappeared almost completely soon after the injection and has not reappeared since.

CASE XIII.—Butcher, aet. 60. General rheumatic condition for the last twenty years. Blood pressure 190 mm. One 50 mcgm. radium injection reduced the pressure to 160 mm. in four days and it settled at 150 mm. at the end of a month. Patient in absolutely good health at the end of a year.

CASE XIV.—Mrs. C., aet. 50. Subacute rheumatism. History of either neuritis or rheumatism for the last two months. Pressure 200 mm., following the administration of 50 mcgms. radium element intravenously, reduced in five days to 160 mm. and 150 mm. after three weeks. All rheumatic symptoms disappeared completely in about ten days. Reports in very fine health after a year; pressure 160 mm.

CASE XV.—Mrs. R. P., aet. 50. Suffering from neuritis for the last six years. Could not sleep more than an hour in the night. Pain in the left arm, and from base of skull down to the lumbar region almost constantly. Blood pressure 205 mm. No form of treatment produced any noticeable change either of the neuritis or blood pressure. Injected 50 mcgm. radium element intravenously. Pressure 180 mm. the next day—170 mm. at the end of three weeks. Pain almost gone except in a small spot at the base of the skull. Second injection caused the pain to disappear completely in twelve days. Patient reports every month. At the end of a year no pain had recurred—patient can sleep from ten to twelve hours every night and take a nap in the afternoon; has gained thirty pounds and says she feels twenty years younger.

CASE XVI.—Mr. W., coal dealer, aet. 65. Blood pressure 230 mm. Violent headaches, dizziness, advanced arteriosclerosis. No improvement under any form of treatment for the last ten years. One 50 mcgm. injection of radium element lowered the pressure 50 mm. in a period of four weeks. A year from the injection patient has pressure of 175 mm. and has had no recurrence of his former symptoms.

CASE XVII.—Mr. S., aet. 72. General arteriosclerosis. Complained of feeling heavy together with a general sensation of malaise and anxiety. Rheumatic pains for the last twenty years, subacute attacks more frequent and compel him to stay in bed about once every two months for a period of one to two weeks. Blood pressure 240 mm. One injection (50 mcgm. radium element) brought the pressure down to 190 in five days. All rheumatic symptoms had disappeared in four weeks. Patient reports every month and is very grateful to radium treatment. After the period of a year no symptoms have reappeared and the general condition is very good—blood pressure 190 mm.

CASE XVIII.—B., aet. 45. General condition bad; no other symptoms except increasing weakness, loss of weight and anxiety; almost constant headache. Blood pressure 260 mm. reduced to 210 mm. in four days with an injection of 50 mcgm. radium element; 200 mm. in seven days. Patient reports often and at the end of six months has gained thirty pounds, feels fine and pressure is 180 mm.

CASE XIX.—Failure. Patient with pressure of 230 mm. General malaise, but not sufficient to prevent him working. Visited the best clinics for the last two years. Failed to reduce the pressure with diet, treatment, etc. 50 mcgm. radium element in the form of an intravenous injection reduced pressure 11 mm. in six hours. Next day pressure went back to 230 mm. There is no trouble with the kidneys or with the circulatory system. Opportunity for further treatment with radium was not possible. Simply a case of idiopathic hypertension and possibly would not have been influenced.

CASE XX.—Mrs. L. S., housewife, aet. 59. Marked

depression with melancholia. Three members of her family died of apoplexy. Severe vertigo, insomnia, asthmatic tendency, abdominal distention, fairly advanced arteriosclerosis with nephritis, anemic; hemoglobin 70 per cent. Pressure 180 mm. In this case 50 mcgm. radium chloride was given intravenously. Ten days later pressure 160 mm.—symptoms somewhat relieved. A second injection, 25 mcgm., was given resulting four days later in a pressure of 145 mm. Two weeks later pressure was found to be at 160 mm. Radium solution in doses of 2 mcgm. ordered every day. Pressure taken twice weekly for six weeks of this treatment showed an average of 155 mm. Nephritis cleared up. Asthma disappeared, deep respiration, patient less nervous and rested well, took up her housework with renewed interest.

In conclusion may I leave just one thought with you; I would have you agree with me that we are dealing with a most potent force, remarkable in its powers to activate biochemical processes. It is commended to you only as an adjunct, to be used in conjunction with all remedies recognized as effective in influencing metabolism. But few of my friends here to-night have ever listened to a paper on the theme of your president's choice—to my knowledge, it is the first time in this country that the subject has been presented. Radium in this field, received even as its introduction a startling statement, for in a very recent issue of the MEDICAL RECORD an authority unhesitatingly proclaims as follows: "The greatest enemy of the cardiovascular-renal patient is the supposed specific, whether it be electricity, radium, etc." How science must hold its head low and weep, or shall I say smile? In my early days of practice I remember my antagonism to diphtheria antitoxin. Quinine was almost lost in a veil of ridicule. Chloroform had its hard fight for recognition, and even to-day you will hear of the unbelief in salvarsan, so we can be both charitable and patient. If you assume that I have erred in conservative expression let the excuse be that the worker in radium therapy grows enthusiastic as he manipulates that agent of greatest known energy, the product of the Almighty's laboratory, "Mother Earth."

Pulmonary Syphilis.—H. R. M. Landis and P. A. Lewis believe that pulmonary syphilis of a latent type occurs far more frequently than is usually supposed. The form to which they call attention is that in which the localization occurs in the apices of the lungs. This type of the disease may in certain cases simulate early pulmonary tuberculosis with such fidelity as to deceive us entirely.—*American Journal of the Medical Sciences*.

HEALTH INSURANCE.

By E. H. LEWINSKI-CORWIN, Ph.D.,

NEW YORK.

EXECUTIVE SECRETARY, PUBLIC HEALTH COMMITTEE, N. Y. ACADEMY OF MEDICINE.

SOONER or later, and the sooner the better, we shall have in this country social insurance against the contingencies caused by sickness. The direct relation sickness bears to poverty and to other social evils and how those in turn react in producing sickness are matters too well known to be dealt with in this short paper, designed to bring before the medical profession of New York some of the problems involved in a health insurance plan of such great import as that proposed by the committee on social insurance of the American Association for Labor Legislation.

The social insurance committee proposes that every person gainfully employed and earning less than \$1,200 be compulsorily insured against sickness, two-fifths of the cost of the insurance to be borne by the worker, two-fifths by his employer, and one-fifth by the State. I take it that the medical profession as such is not keenly interested in the details of the general administrative organization of such a scheme or in the social philosophy underlying the measure. As to the first it may, however, be stated that it is proposed to make the mutual local funds, either in one trade or in several trades, the carriers of insurance, to be governed jointly by employers and employees under State supervision. As to the social justice of the plan, it may suffice to say that it tends to put on a higher social scale the hundreds of thousands of persons from among our working population who, under present conditions, must resort to charity in cases of prolonged illness. Health insurance does away with much, if not all, of the present-day medical charity and costs but little, if any more. We do not let our sick poor die for want of medical care, or their families starve. Health insurance aims at nothing else than making systematic provisions for them. But instead of employing the present haphazard methods, which are often ineffective and reduce self-respecting people to the level of recipients of charity, it proposes to handle the matter rationally and without offending the sensibilities of our industrial workers.

The number of persons of both sexes, over fifteen years of age, who are gainfully employed is over thirty-five millions in this country. Compilations based on German figures of the average duration of disability and on the estimate that about 40 per cent. of the persons gainfully employed suffer more or less incapacity during the year, place the number of days lost through sickness at two hundred and ninety-seven millions per annum, and the number of persons afflicted at fourteen millions per annum. Only a part of these fourteen millions of people receive private medical treatment. A great number of them, suffering from minor and less acute ailments, seek relief in dispensaries. The number of dispensary visits in this city alone amount to more than four million a year. The treatment given in most of the dispensaries is unsatisfactory. A health insurance law, enabling persons with moderate incomes to command the paid services of physicians is, *per se*, a great advance in health work. It affords, moreover, a great many additional opportunities for effective preventive measures. Prevention of disease should be one of

the primary objects of a measure of this kind, just as prevention of accidents is a primary motive of workmen's compensation laws, and nobody is better qualified than the medical profession to point out how best these ends of preventive medicine could be served by an insurance law.

Health insurance, if it is to succeed, must have the whole hearted support of the medical profession. It seems, therefore, of paramount importance that before a measure of this kind becomes a law it should have the benefit of the well-considered advice of the medical profession and should be drawn in such a way as to meet the just demands of the profession, so that it may produce no hardship to those on whom the success of the measure chiefly depends. With a view of stimulating discussion and of pointing out some of the medico-administrative problems involved, I have prepared this paper. It does not intend to suggest any solution, but merely to raise questions and to promote discussion, as a result of which the wishes and views of the medical profession could be made generally known.

A. General and Historical.—The serious social consequences entailed by sickness have very early led the industrial workers of the Continent and of Great Britain to devise some means of affording relief through the establishment of mutual aid associations. These societies have, throughout the nineteenth century played an important part in the economic life of the European countries and their activities covered a great number of various forms of mutual assistance. But with the growth of the modern fabric of industrial life, the extensive application of machinery and the concentration of large masses of population in limited areas, the old methods became inadequate and workmen's insurance was put on a broader social basis. Accident insurance has been universally made a part of the cost of production and provisions for insurance against sickness have become a matter of governmental concern and regulation in almost every country of Europe.

Generally speaking, there are two types of workmen's insurance against sickness: the system of voluntary insurance, usually subsidized by States or municipalities, and that of compulsory insurance. In the first system the individual is left to make provisions for himself through the medium of State-regulated mutual aid societies which in the great majority of instances receive donations from the State or municipality to help sustain them. The subsidies are designed to stimulate thrift and self-help by adding certain amounts, graded in accordance with the individual's endeavors, to the benefits granted by the societies which are entirely dependent on the premiums of their members. Under the compulsory system, all persons of a certain description are compelled to insure themselves in specified institutions and the premiums are paid in part by the insured, by their employers, and by the State or municipality.

France, Belgium, Italy, Spain, Sweden, Denmark, Finland, and Switzerland have voluntary insurance systems subject to various degrees of governmental supervision and working with various degrees of success. Denmark has achieved remarkable success under its plan of operation. In other countries voluntary insurance has been more or less of a failure. Even in Belgium, noted for the thrift of its population, "it is the élite of the working class alone that can stand the cost of sick insurance."

The plan of compulsory insurance inaugurated in Germany in 1883 and copied, with such changes as best fit their administrative and political conditions, by Austria in 1888, Hungary in 1891, Luxemburg in 1901, Norway in 1909, and more recently by Great Britain, Russia, Roumania, and Serbia, is being recognized as the more satisfactory and effective method of solving the problem, and is being recommended for adoption in the several States of this country by the American Association for Labor Legislation.

In the United States there is a great variety of unrelated private endeavors to meet the problem of insurance against sickness. We have workmen's circles, lodges, trade union funds, fraternal orders, establishment funds operated by corporations for the benefit of their employees, commercial casualty, and health insurance companies, etc. All these individual endeavors should be woven into one coherent entity.

B. Problems Involved.—Health insurance, although one of the earliest forms of industrial insurance, is at the same time the most difficult to administer. For no other form of insurance is it so difficult to secure an adequate actuarial basis; no other form of insurance deals with so large a number of conditions, contingencies, and circumstances, and no other branch of insurance is so liable to abuse. Feigning sickness, malingering, and valetudinarianism are grave obstacles to the successful administration of sickness insurance. The attainment of a uniform efficiency of medical service and of an adequate control over the administration of the medical benefits, and the establishment of a satisfactory basis for the relations between the insurance carriers, the medical practitioners, and the insurance beneficiaries are problems for which no standards have as yet been devised.

When the British national health insurance law was enacted the medical profession found many of its provisions unacceptable, and then laid down the following six cardinal principles:

1. An income limit of £2 a week for those entitled to medical benefits.

2. Free choice of doctor by patient subject to consent of doctor to act.

3. Medical benefits to be administered by insurance committee and not by friendly societies.

4. The method of remuneration of medical practitioners adopted by each insurance committee to be according to the preference of the majority of the medical profession of the district of that committee.

5. Medical remuneration to be what the profession considers adequate, having due regard to the duties to be performed and other conditions of service; and

6. Adequate medical representation among the insurance commissioners on the central advisory committee and on the local insurance committees, and statutory recognition of a local medical committee representative of the profession in the district of each insurance committee.

C. Specific Questions to Be Considered by the Medical Profession.—Is it desirable to formulate similar principles before a health insurance law is passed in this State? If so, what should they be?

The following is a series of questions, upon the answer to which will depend the success or failure of health insurance insofar as the medical aspect of it is concerned:

1. Should the patient be free to choose his physician?

2. Should the physician be free to reject patients who have selected him or who were assigned to him?

3. Shall there be a medical "panel" as in England, and, if so, who shall be responsible for it: (a) county medical societies? (b) special *ad hoc* organized medical corporations?

4. Shall the diagnosis of the attending physician be the final basis for the granting of benefits or shall it be subject to revision and, if so, by whom: (a) by the insurance carriers? (b) the medical society responsible for the "panel"? (c) by observation in a hospital?

5. Should there be uniformity of standard in adjudging the extent of invalidity or disability? If so, is it possible to enforce such a standard without employing a special expert staff of medical men whose sole duty it will be to look after the invalidity cases?

6. Under whose direction should such a staff be: (a) the State Insurance Board? (b) the insurance carriers? (c) the medical organizations?

7. Should the patient have a right to appeal from the judgment of the physician passing on the extent of his invalidity?

8. If so, would not this practice be very costly and entail constant litigation? Then, who should sit in authority over the judgment of the special medical expert: (a) the State Insurance Board? (b) the insurance carriers? (c) the medical organizations?

9. What shall be the basis of compensation of physicians: (a) the number of visits made and the services rendered? (b) a monthly or annual salary? (c) an average monthly or annual per capita fee?

10. Who shall appraise the value of services rendered and the number of visits needed, in case the first method of compensation be adopted?

11. Would not the other methods of compensation result in indifferent and slipshod work?

12. Who shall decide how many patients should be allotted to a physician?

13. Should not the fees for treatment of workers in well paid trades be higher than in the case of workmen in low paid occupations?

14. Should the insurance carrier deal with the individual physician or with the county medical societies or special medical organizations created for the purpose?

15. Should such medical bodies be charged with preparing the "panels" and be responsible for the physicians recommended?

16. Should not the patient be made to pay a part of the physician's fee (over and above the insurance premium) in order to reduce the possible number of unnecessary calls made by hypochondriacal patients?

17. How shall malingering best be controlled?

18. Who shall exercise control over the physicians in their treatment of insured persons: (a) the insurance carrier? (b) the medical society?

19. Outside of acute surgical conditions and contagious disease cases, who shall decide whether a patient should be sent to a hospital?

20. Will the health insurance law act as a deterrent to hospital practice?

21. Could not the existing dispensaries be made an important branch of the service by increasing their staffs of paid visiting physicians and nurses, a procedure which may be made possible by adequate financial arrangements with the insurance carriers?

22. Could the services of specialists be obtained in any other way, except through the dispensaries?

23. Could not the health insurance law be made a potent factor in raising the dispensaries to a high level of usefulness and efficiency?

24. Could not the health insurance law provide for periodical physical examination of all of the insured and in this way act as an important stimulus to the preservation of health?

25. Should the dependent wives and children of the insured men be made beneficiaries under the act?

26. Would not the inclusion of women and children in the health insurance law (a) afford needed protection to maternity, and (b) make possible an improved control of contagious diseases?

27. Should the State Commissioner of Health and the local health officers be made members of the State Insurance Board and of the local insurance committees, respectively?

28. Would not the economic status of the great body of physicians improve and be put on a safer basis than at present if the stipulated remuneration for services under the health insurance act were made reasonably satisfactory?

D. Literature on Health Insurance.—Experience alone can supply the best answer to many of the questions raised. No law can be made perfect when first framed. Many adjustments and changes become necessary when its shortcomings, due to unforeseen conditions, become visible after a period of actual operation. No foreign practice can be an absolutely trustworthy guide, because of the pronounced differences of the economic and social environment, the character of the population, and its national traditions. Many fundamental principles and standards apply, however, to all civilized communities. A study of the methods employed in other countries and the results achieved may, therefore, be of great service in forming one's opinion on the subject and in arriving at conclusions with reference to some of the questions entering into the problem.

The literature concerning health insurance is vast, particularly in foreign languages. Of the English and American publications outside of official and non-official reports, as most helpful to busy readers, the following few may be mentioned:

REDUCTION OF OBESITY.*

BY ALBERT WARREN FERRIS, A.M., M.D.,

SARANAC LAKE, N. Y.

It is elementary to say that during digestion, assimilation, respiration, and excretion the food taken into the body breaks down into simpler compounds or is transformed into new compounds. Every act, whether it be muscular and voluntary, or nervous and involuntary, consumes energy. If we would prevent wasting, we must produce in the body an equivalent amount of energy obtained from food to replace the energy that is being consumed. The force that holds the food elements together is called potential energy, and the name kinetic energy has been given to the force into which potential energy is transformed during the breaking down of food into simpler compounds. The process is not clearly understood, but there is a close parallel to the combustion of fuel, since it is probably a complex oxidation.

Fat is to be regarded as mere fuel, accumulated for future use. It should furnish most of the heat energy, oxidizing rapidly and thus sparing the protein elements that would otherwise be wasted. It should constitute about 20 per cent. of the body weight. A considerable variation above this proportion constitutes obesity.

We encounter two classes of corpulent persons: first, those who are very stout, yet are active and otherwise healthy; second, those who are moderately or excessively obese and are diseased. Those constituting the first class rarely desire reduction, and its employment must be decided upon their personal appearance and their state of health. If they are not gaining weight, they rarely care to submit to the process, though some will adopt a diet which will prevent further accumulation of fat. The persons constituting the second class generally require reduction, for they suffer from difficulties due to impeded circulation, such as dyspnea, early fatigue upon exertion, and cold extremities, as well as from atony of the intestines and myocardial degeneration. A removal of even a moderate amount of fat will quickly improve the functional powers of the lungs, the liver, and the muscles, if the person be not aged.

Efforts at reduction at home are usually futile, because of the want of sympathy offered by the family, the difficulty in securing proper individual diet, the temptation provided by the daily sight of all kinds of food, and the urging of members of the family to be less strict than the physician has directed. Besides, the regularity and proper total of exercise demanded are difficult to secure during the performance of usual duties in the home or at the place of business. Reduction treatment is easiest and vastly more successful in an institution or at a health resort, where definite diet can be prescribed and furnished, and where, in an atmosphere of routine and obedience, there is less temptation to transgress and every encouragement to persevere, through the community of interest felt by every one and the force of numerous good examples of obedience daily before one's eyes. Unless a settled determination and a conscientious effort exist in the mind, there is no use of attempting reduction of corpulence. Indulgence in alcoholic beverages, course dinners, extra suppers after theater, etc.,

*Read at the Ninth Annual Meeting of the Fourth District Branch, Saranac Lake, October 12, 1915.

defeat all measures that may be taken. These difficulties are oftenest encountered in people between the ages of 30 and 40 years, the very ones who offer the best chances for entirely successful results.

Special caution is necessary on the part of the physician in undertaking the reduction of persons over 60 years of age (as well as in somewhat younger people) if signs of senescence appear. If senile decay is approaching, reduction of obesity will accelerate it, and the patient, even if relieved of the burden and danger of excessive fat, will be much weaker at the close of the treatment. Yet the danger to very fat people of any age from infectious diseases, heart lesions, lung diseases, and arthritis, or even from simple overstrain of the heart, must be seriously considered before deciding to advise against reduction.

The most important class of disorders which coexist with obesity embraces diseases of the circulatory system, including valvular lesions of the heart, myocarditis, weak cardiac muscle, and arteriosclerosis, as well as emphysema and extensive adhesive pleuritis. In the three last mentioned conditions the heart is called upon to perform increased work, and is often hypertrophied, if not also dilated. The mere relief from excessive labor experienced by the heart with the removal of the heavy fat, allows, in many cases, restoration of normal action and diminution of the signs of decompensation. This accomplished, measures such as a course of Nauheim baths together with resisted movements should be instituted, and in a very large number of cases many years of life in comparative comfort may be added to the span of existence of these patients. The best results, of course, are reached if the entire treatment is instituted before any signs of failing compensation appear, and alarm is taken at the first signal of disorder of the circulatory apparatus. In very serious cardiac cases, Groedel of Nauheim advises treatment of the heart condition first for a considerable period before beginning the reduction of fat, and von Noorden agrees with him. Frequently an intermittent reduction is best; that is, securing a loss of four or five pounds during a week and then proceeding more slowly, removing a similar amount in a month, the patient meanwhile being allowed a diet liberal enough to preserve the weight at a fixed amount. Hydrotherapy to stimulate the peripheral circulation is administered during the interval, and then the reduction should be resumed.

Obese patients suffering from chronic interstitial nephritis should be treated exactly as carefully as those with grave heart disorders. In these cases it has been found necessary to support the heart, but it is very undesirable to give the patient such a diet as will cause a decided increase of body weight beyond that carried by the patient when he was apparently in good health. That is, a thin patient who was discovered to have contracted kidney disorder should not be so over-fed as to take on a considerable quantity of fat, lest he suffer attacks of dyspnea and even precordial pain. A few cases of nephritis with these symptoms can be relieved promptly by reducing their weight.

Many obese people suffer constantly from exhausting bronchitis. In these cases relief from the accumulation of intrathoracic fat permits the lungs to make larger excursions, and thus encourages free circulation of the blood stream through the pulmonary capillaries, and gives grateful relief. Often these patients have been improperly treated by sub-

jecting them to a course of alkaline cathartic waters, at some spa, without any result except a decided diminution of their strength. The proper diet, exercise, and massage will afford relief in a large percentage of these cases.

How rapidly may the obese patient be reduced? The answer is, Generally, by 5 lb. a week; often so rapidly as to average 7 lb. a week for a few weeks.

The diet is a very important part of the treatment. Many attempt reduction, but demand that successful measures be instituted which will not interfere with the usual routine of their lives including liberal indulgence in food and beverages, and avoidance of all regular exercise. Such patients demand internal medicines that will cause "melting away of the fat," and often become the victims of advertising quacks; or they dose themselves with pickles or vinegar and starve themselves indiscriminately. The constant use of acids disorders the digestion, and starvation, of course, does decided damage since acidosis is easily set up. In my opinion, all the drugs used to cause rapid reduction, including thyroid extract, are very dangerous to the patient, if they diminish the weight.

At the Glen Springs, Watkins, three standard diets are employed in cases of obesity, varied according to the condition of the individual patient. I will quote these diets entire, since the illustrative case, the record of which I will append to this paper, was treated successfully at this institution.

DIET IN UNCOMPLICATED OBESITY.

Breakfast: Two soft boiled eggs or broiled steak, 40 grams; zwieback or graham bread, 75 grams; coffee, 200 c.c., with milk, 20 c.c.

Luncheon: Consommé, 100 c.c.; broiled steak or chops, cold roast beef, cold roast mutton, or cold roast chicken, 200 grams; portion of salad with French dressing (made with lemon juice); zwieback or graham bread, 25 grams; fresh fruit, 150 grams; water, 250 c.c.

Dinner: Beef, mutton, lamb, or poultry, 200 grams; portion of salad with French dressing (made with lemon juice); zwieback or graham bread, 25 grams; cheese, 5 grams; water, 250 c.c.

Note. Between each two meals 100 c.c. of water may be taken if desired. Total calories in 24 hours, 2,065. Total fluids in 24 hours, 1,100 c.c.

DIET IN OBESITY WITH CHRONIC JOINT DISEASE.

Breakfast: Small serving of broiled white fish, mutton chops, beef steak, or lean ham; one slice of well-toasted bread without butter; one cup of tea or coffee (8 ounces) with skimmed milk and no sugar (saccharine or glycerin may be used to sweeten).

Luncheon: Small serving of cold chicken, game, beef tongue, lean ham, or one poached egg; small serving of any two of the following vegetable: Spinach, lettuce, water cress, string beans, celery, turnips, parsnips, beet tops, cauliflower, artichokes. Small serving of salad with lemon juice (no oil or vinegar). Stewed or baked apple or pear without sugar or milk. No fluids.

Dinner: Beef consommé or bouillon (8 ounces). Small serving of broiled or boiled fish without sauce, broiled or boiled mutton, game or fowl (with little fat). Same choice of vegetables as at luncheon. Two gluten or almond biscuits. Stewed fruit without sugar or milk. Tea or coffee (8 ounces) with skimmed milk and no sugar.

DIET IN OBESITY WITH HIGH SYSTOLIC BLOOD PRESSURE.

Breakfast: Coffee, 6 ounces, no cream or sugar. One soft boiled or poached egg, 60 c. Two thin slices of white, rye, or graham toast with no butter, 150 c. One orange, one-half grapefruit, ordinary serving of strawberries, one peach or one apple, 50 c. Total calories, 260. Total fluids, 6 ounces.

Luncheon: Any two of the following: Egg plant, asparagus, turnips, beets, spinach, cauliflower, string beans, Brussels sprouts, 100 c. Salad of any one or two of the following: Lettuce, cucumbers, tomatoes, cabbage with vinegar or lemon (no oil) 50 c. One portion of the following fruits: Cantaloupe, watermelon,

strawberries, apple, orange, grapefruit, 50 c. Two ordinary slices of bread, 150 c. Four grams of butter, 30 c. Total calories, 380. Total fluids, none.

Dinner: Choice of chicken, broiled or roasted, or broiled fish, 75 c. Mixed pickles and celery, 25 c. Any two of the following: Beets, turnips, cabbage, cauliflower, asparagus, egg plant, string beans, squash, green peas, onions, 100 c. Salad of any two of the following, with lemon or vinegar (no oil): Cucumbers, tomatoes, cabbage, 50 c. Choice of same fruits as at luncheon, 50 c. Two slices of bread with no butter, 150 c. Black coffee, 4 ounces, without cream or sugar. Total calories, 450. Total fluids, 4 ounces.

NOTE.—Midway between each two meals 100 c.c. of water may be taken, if desired.

In many cases, it is undesirable to give meat in any form, and a protein of corresponding value may be substituted where meat or fish has been suggested in the diet lists quoted.

Hydrotherapeutic measures are of great value in many of these cases, in fact, are well nigh indispensable. A convenient method for the patient, if living in a health resort where the proper facilities are available, is to be subjected to a hot bath in a fairly strong brine, the temperature being increased while the patient is in the bath up to the limit decided by the physician. After the bath, the patient receives a cool spray, is wrapped in a blanket, after being dried, and rests for twenty minutes, and then goes out into the air. This bath should be given three times a week. On alternate days, an electric light cabinet bath is given to the point of full sweating, as prescribed by the physician, and immediately afterward the patient is placed in a hot pack for an hour. At the end of the hour a cool spray is administered and the patient is rubbed thoroughly dry. On at least one day in the week no treatment should be given and the patient should be urged to rest for most of that day.

The exercise, which is important, should be carefully chosen by the physician according to the patient's strength and such complicating diseases as may exist. Massage, passive motion, Swedish exercises, and out-of-door walking, together with calisthenics directed to groups of muscles in the entire body, and forming a regular part of the treatment, are essential in restoring tone to muscles that have been inactive from being so heavily overlaid with fat as to have suffered from impeded circulation.

A method of reduction which may be pursued in the case of the weakest patient is known as the Kellogg-Bergonie Method, in which the sinusoidal current of electricity is used. As should be better known, this current was discovered by Dr. John H. Kellogg of Battle Creek, Mich., and was described and used by him about six years before d'Arsonval also discovered it. By this method of reduction the patient is placed upon a table and the sinusoidal current is administered to several groups of muscles at once, causing rapid contractions in them and thus securing an output of energy and a rapid consumption of fatty tissue in their neighborhood without calling upon the patient for any voluntary activity. The amount of work done by the groups of muscles may be increased by loading upon them sand bags of varying weights, until the patient is bathed in profuse perspiration, which naturally results. By this method the irksomeness of pursuing regular and repeated exercise is avoided and the brain and spinal cord remain at rest, except that the heat centers of the spinal cord are stimulated to rapid and repeated activity.

Both these methods, that by hydrotherapeutic procedure and exercise and the other by the use of

the sinusoidal current, owe their efficacy to the combustion of fat and the production of water which is lost as perspiration. We know that if the internal temperature be raised, an excessive amount of sweat is poured out in the effort of the body to cool itself. Von Noorden says that 100 grams of fat yield 107 grams of water during the process of combustion. Atwater and Benedict, in their experiments of a few years ago, ascertained that during the copious sweating incident upon hard work, the amount of water lost from the skin was eight times the amount of normal perspiration and represented the loss of 1 gram of nitrogenous excreta in five hours. Thus, the sweat glands can in some degree be made to assist a function of the kidneys, and a further safeguard is thus offered to the heart or kidney patient by the process of reduction of fat.

The single case, the records of which I will quote, was treated by me at the Glen Springs, Watkins, N. Y., during a period of eighteen weeks, actual treatment covering only fourteen and a half weeks, since the patient went home for a period of three weeks in the midst of the treatment, returning to finish it after this brief absence.

The patient was an unmarried woman, aged 63, living in comfort, devoting a large part of her time to philanthropic and benevolent enterprises, very conscientious, and expending much energy upon the philanthropic work undertaken. She had been gaining flesh progressively for twenty-three years. During the past ten years, she had gained with great rapidity. At the age of 27, she had had an attack of "nervous prostration," due to anxiety and the work of preparation connected with the marriage of a sister, and the dread of separation from her. She reported that she felt the effects of this attack for many years. While motoring in the country recently, she felt as if she had "a rush of blood to the head," and believed she had experienced a sunstroke. Ice had been applied to her head for several hours and she felt very weak for two days. For a considerable period of time she suffered from vertigo, and frequently her sight seemed blurred, and her vision distorted. Owing to the vertigo, she had fallen and bruised herself two days before admission. She further reported that during the previous winter, after walking slowly up a moderate grade for two blocks in a street near her home, she had a feeling of oppression and distress in her chest with dyspnea which lasted for thirty hours.

Her mother had died at 66 of "heart disease or apoplexy"; her paternal grandfather had died of "paralysis" at the age of 70; and four brothers and sisters of her father had died of "kidney trouble." No other significant facts were elicited concerning her family history. Her mother was extremely stout and one brother was quite stout.

As to her personal habits, she walked very little out of doors, but took long drives in her automobile daily; she ate no meat and aimed to take less food than previously; she was drinking five glasses of water a day; she never had used any alcoholic beverages. She complained occasionally of headache, dyspnea, vertigo, blurring vision, palpitation upon exertion, gas in the stomach, almost daily, and edema about the ankles.

Physical examination revealed a condition which is summarized in the following notes:

General Appearance: Very obese, florid, white, female adult.

Hair: Silver, abundant. Apparent age 65 years.

Height: Five feet 4½ inches with heels.

Pupils: Widely dilated, equal, regular, react quickly to light and normally for distance.

Scleræ: Yellow and injected. *Conjunctivæ* very red.

Tongue: Protrudes straight, dry, red, coated. Mucous membrane red.

Tonsils: Very small. *Pharynx* red.

Chest: Right breast tender from injury.

Lungs: Hyperresonance on left side. Expiration prolonged and of high pitch, left posteriorly. No râles.

Heart: P. M. I. not obtainable. Dullness: Upper border of third rib to fifth interspace, 1 inch to the right, 5½ inches to the left. Oblique diameter, 6½ inches. Soft systolic murmur at apex transmitted 1

inch to the left, heard over whole heart, faintly at ensiform. Systolic murmur at base, loudest over right third interspace. Muscular quality fair. Aortic diastolic sound accentuated and greater than pulmonary diastolic sound.

Abdomen: Wall $2\frac{1}{2}$ inches thick, fairly firm. Mass (?) central line, above umbilicus. Slightly tender. Questionable fluctuation.

Lymphnodes: ?

Liver: Not palpable or tender. Dullness fifth rib to 1 inch about costal margin. Vertical diameter $2\frac{3}{4}$ inches.

Spleen: Not palpable. Dullness eighth rib to eighth interspace.

Kidneys: Not palpable.

Stomach: Lesser curvature at eighth rib; greater curvature $2\frac{3}{4}$ inches above umbilicus. Vertical diameter $3\frac{1}{4}$ inches.

Blood pressure (Stanton instrument, patient recumbent, auscultatory method): Systolic, 185; diastolic, 84; mean, 135; pulse pressure, 101. **Pulse:** Recumbent 104, regular, good strength and volume. High tension. Pulse on standing 108, regular, good strength and volume. **Arteries:** Radial, palpable. Brachial, not obtainable; temporal, not palpable.

There was decided pretibial edema.

Summary: Coated, dry tongue, emphysema, systolic murmurs, high blood pressure, tachycardia, palpable radials, edema of ankles.

The **Urine Examination** provided the following data: Total quantity, 1,100 c.c.; specific gravity, 1.012; reaction, acid; no albumin; no glucose; appreciable trace of indican; triple phosphates, few leucocytes, considerable epithelium.

The patient's weight, stripped, was $221\frac{1}{4}$ pounds.

She was put upon the following treatment: Three electric light baths a week, at 110° , until full sweat, followed by blanket pack and spray; deep massage three times a week on alternate days; Swedish and Zander machine exercises daily; diet list for "obesity with high blood pressure," already quoted modified for her individually; voluntary exercise to consist of one mile walk on the level in the morning, repeated in the afternoon daily. After six days, the temperature of the electric light bath was increased to 115° , and after a month it was increased to 120° . Ten days after admission, the Nauheim course of baths was begun, the patient taking three a week on alternate days. Each bath was preceded by the application of two or three hot cloths to the hips and stomach to produce a good sweat before entering the bath tub. The patient voluntarily increased her walking exercise until four weeks after admission she was walking five miles daily without fatigue. This amount was reduced to four miles at once. At this time, her weight had decreased to $195\frac{1}{4}$ pounds, showing a loss of 26 pounds, in as many days.

A few days later, she showed her first symptoms of nervousness and annoyance at small matters, and so her exercise was reduced at once to two miles a day, and she was urged to rest on the bed two or three hours during each day.

Her treatment continued uneventfully with slight changes in its application, her systolic blood pressure decreasing to 169, later to 134, and rising again to 145. A little over three months after admission, she made her first attempt at hill climbing accompanied by the physician, walking up a moderate slope easily, with no dyspnea or tachycardia, and with enjoyment. A week later she repeated the effort, walking up the hill in the face of a cold wind without distress.

On discharge, she felt well and increasingly strong, and rejoiced in the loss of $53\frac{1}{2}$ pounds, departing with a weight of $168\frac{3}{4}$ pounds. A résumé of her examination report at departure reveals the following data:

Heart: P. M. I. not obtainable. Dullness lower border third rib to fifth interspace, $\frac{7}{8}$ inch to the right, 5 inches to the left. Oblique diameter $6\frac{1}{4}$ inches. Soft systolic impurity at apex not conducted. Pulmonary diastolic sound greater than aortic diastolic sound, both slightly accentuated. Muscular quality good.

Stomach: Lesser curvature at seventh rib; greater curvature 2 inches above umbilicus. Vertical diameter $3\frac{1}{2}$ inches.

Blood pressure phases (Stanton instrument, auscultatory method, patient recumbent): 145 (systolic), 143, 138, absent, 78 (diastolic); mean, 102; pulse pressure, 67.

Pulse: Recumbent 72, regulator, good strength and volume.

Arteries: Radial, brachial and temporal slightly palpable.

No edema.

During the month succeeding her return home, she felt at times "lightness in the head" and a slight uncertainty, and the resumption of household cares and her philanthropic duties for a few weeks seemed somewhat difficult. These symptoms immediately disappeared and she remained in excellent condition, mental and physical, during the winter and spring, and in the following summer carried out a trip to a foreign country taking with her a companion unaccustomed to travel for whom as well as for herself she made all arrangements of every sort concerning hotels and railroad travel without fatigue or difficulty, but with an increasing activity and a return of the ability she had experienced ten years before.

She gradually resumed largely her former diet, until with very few restrictions she was eating the food that she had preferred to eat before her treatment began, and she did not gain in weight during the following year, but decreased 5 pounds further, shortly after her return home, thus reaching a total loss of 59 pounds. The reduction was effected in 1912, and since that time the patient has on two occasions gained small amounts of flesh, which she was able promptly to lose again by cutting starchy and sweet foods out of her diet for a couple of weeks on each occasion.

THE DANGERS OF HASTY DIAGNOSIS OF PULMONARY TUBERCULOSIS.*

By MAURICE FISHBERG, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF TUBERCULOSIS, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL, MEDICAL COLLEGE; ATTENDING PHYSICIAN, MONTEFIORE HOME AND HOSPITAL FOR CHRONIC DISEASES.

FOR over thirty years the profession has been agitating that to prevent and to cure tuberculosis the disease must be recognized early; some have even been able, or they at least desired, to discover it in the so-called pretuberculous stage, which I take to mean before the patient is sick with tuberculosis. Indeed, recent medical literature abounds in articles full of statistical data showing that a large proportion of patients are sent to institutions for the treatment of phthisis in the advanced stages of the disease and the general practitioner has been made the goat—he is rather late in recognizing tuberculosis and as a result his patients suffer from prolonged disease, misery, and perhaps death. Other articles bring figures showing beyond any doubt that the general practitioner is blameless; that the patient is at fault in most cases because he applies to his physician for diagnosis and treatment when the disease has made deep inroads into his lung.

However it may be, the aim has been "to get them early"—in the incipient stage. And all efforts have been made in this direction so that at present it seems to me that in some clinics everybody who submits to an examination of the chest for any cause is at once put down as a suspect; in fact, often considered tuberculous, just as a man who is accused and indicted for a crime is considered guilty in some parts of the world till he proves to the satisfaction of those properly fit or authorized to judge, that he is innocent, or not tuberculous as the case may be. And this is not an easy matter for many innocent or non-tuberculous persons.

In some countries where careful records are kept and published of the results attained in this line of medical work, it was found that the consequences of the policy of considering every "suspect" as sick with

*Read before the Hudson County Tuberculosis Hospital and Sanatorium Association at Jersey City, N. J., November 8, 1915.

tuberculosis have been disastrous. Thus, in Germany it was found some years ago that many of the "incipients," made eligible for admission to sanatoriums, were fit for military service with all its hardships. What is more, they were enrolled into the army and they served for three or four years, returning home hale and healthy. At present, since the outbreak of the great European war they have found in Germany that many of the patients with "incipient tuberculosis" kept in the sanatoriums at the expense of the public could be sent to the trenches and that they make good fighters. Indeed, Blömel, one of the authoritative writers on tuberculosis, has made a study of the problem recently and has arrived at the conclusion that about 80 per cent. of the incipient cases in the German sanatoriums are not at all sick or they suffer from some other diseases, mainly nontuberculous apical lesions, and he urges the military authorities to draft them into the army at this critical period when their country is in danger. Dr. Fahr (*Deutsche medizinische Wochenschrift*, 1915, XLI, 1082) reports two cases of suicide of persons who were frightened by a diagnosis of pulmonary tuberculosis. One was even an inmate of a sanatorium for some time. At the autopsy not the least trace of active or healed tuberculosis could be found.

There is little or no harm done in some cases of idlers who present indefinite symptoms and signs of tuberculosis and, in fact, suffer from some nontuberculous apical affection, or neurasthenia, psychasthenia, etc., when they are told that they have incipient tuberculosis and are sent to the country, or to some sanatorium for a few months and perhaps "cured." The vacation does them good and they can well afford it. But this class of patients is in the minority. The vast majority of active people in the world cannot afford vacations and great harm often results from an erroneous diagnosis of tuberculosis.

Here is a case which came under my observation: A hard working artisan with a large family depending on him coughed for a few weeks and presented signs of a non-tuberculous apical induration, known as collapse induration and due to mouth-breathing during childhood; he was told at one of the clinics that he suffered from tuberculosis. He heard of the importance of early treatment and immediately gave up his job, sold his furniture, applied for the commitment of his children to an orphan asylum so that his wife could go out to work. I found it a hard job to convince him that he was not sick with tuberculosis, considering his state of mind after being told that he suffered from a deadly malady; he found it harder yet to raise funds for the purpose of purchasing furniture and rebuilding his home.

Another case shows that even those who have no dependents may be harmed by an erroneous diagnosis made hastily: A young college student, with but one year to finish his education, owing to overwork while preparing for examinations, combined with the symptoms of a common cold, was told that he must drop his studies and retire to a sanatorium. Two months later it was discovered that, excepting for some symptoms of neurasthenia and psychasthenia, which were aggravated by the diagnosis of tuberculosis, he was quite healthy; at any rate, he was not tuberculous. But he lost a year in college; and this may be irretrievable.

Take the case of a business man who is well-to-do and the money necessary to expend for treatment

does not count. But his affairs are in such a condition that they require his constant personal attention if they are to be kept intact. He is told that there is just "a touch" of tuberculosis in his lung and that several months in a sanatorium will cure him. His business may be ruined during his absence and he may never be able to catch up again, as I have seen in several cases.

From the social and economic standpoint a diagnosis of tuberculosis is a serious affair and we should not hurry in making it unless we are sure of our ground.

But it is argued that tuberculosis, to be cured, must be taken hold of in time and that there is comparatively little harm done if a few persons are inconvenienced, provided the vast majority of tuberculous persons are thus discovered in time. Indeed, some writer has stated that the one who will discover a sure sign of tuberculosis in the very early stage will be as great a benefactor of humanity as the one who will discover a cure, because early treatment assures a cure.

This would be important if it were true. But it is not. That all tuberculous patients could be cured if discovered in the incipency of the disease is one of the numerous traditional errors which abound in practical medicine, and the sooner we are rid of this error the better for the patients and for the physicians.

It is not true that every tuberculous patient, even if the most approved method of treatment is instituted the very first weeks that the disease makes its appearance by symptoms and signs, can be cured. There are cases which are malignant from the beginning and climatic, institutional, specific, dietetic, medicinal, and other forms of treatment are each and all of no avail. The fact that we call them acute, galloping, hasty forms of the disease does not alter matters. It is not a question of naming the disease; it is a problem of curing the patient. And this we cannot do at the present stage of our knowledge. This class of patients, whether taken in time or neglected, will pursue along the course of a deadly disease to a fatal termination. In fact, institutions which claim without many reservations that they can cure all cases of tuberculosis if sent to them in time, fight shy of progressive, febrile, and acute cases. And when perchance one of them gains admission, even if the patient has been only a few weeks sick, he is at once bundled up and sent back home under the plea that the climate is not suitable for his case, that he will not be benefited by the institutional treatment, etc., and the mortality is thus kept lower than that in the United States army at the Mexican border.

On the other hand, there is rather undue haste in cases of chronic phthisis. We will not save them all by taking hold of them during the first week of their illness, nor will all those who are not treated during the first six months of their illness perish. This is a fact which we all know, but it somehow escapes our memory when examining a patient. In cases with tendencies to cure, owing to inherent resistance of the organism, the disease pursues a slow, sluggish course; periods of health alternating with periods of illness, and there is always time to make a final diagnosis of tuberculosis. In other words, the patient is not at all harmed by waiting. Indeed, under present methods of management of tuberculous cases nearly all dependent consumptives, and they are in the majority, have to wait for proper treatment, irrespective of

whether the diagnosis has been clearly made or not. We are all aware of the fact that the facilities for institutional treatment, which is the only effective method for dependent consumptives, are wholly inadequate; if all incipient cases were recognized in time, it would be found that hardly 10 per cent. could be accommodated in existing state, municipal, and philanthropic sanatoriums.

As a result of undue haste in diagnosing incipient tuberculosis a considerable proportion of nontuberculous cases are admitted to sanatoriums taking the places of patients with active disease who might be benefited by the facilities these institutions offer. I know of one institution in which there were at one time 50 per cent. of patients with negative sputum, and we are all aware that the majority of these "closed" incipient cases are nontuberculous.

Another thing we must bear in mind: Remaining in a sanatorium is not a simple, harmless vacation for the average patient. The stigma of tuberculosis may stick to him throughout his life. And with the rampant phthisiophobia which has been engendered during recent years in this country the tuberculous stigma is to be dreaded by the average individual. I have known of several cases in which individuals on discovering that the persons courting them had been in sanatoriums refused to marry for fear of the disease. Recently a young woman was sent me for examination to determine whether she was likely to prove a menace while acting as a governess in a private home. Her history was the following: Three years ago she coughed for a few weeks and was sent to a sanatorium admitting only incipient cases, where she remained for two months and was discharged "cured." No tubercle bacilli were ever found in her sputum. Now, on getting a good position she was recognized by another woman who knew her at the sanatorium. She implored her friend to keep the fact that they were both in a sanatorium to herself, but the latter "gave her away." Physical examination showed that she had healthy lungs, and no trace of present or past tuberculous changes could be discovered. But no pleading helped—she lost her position.

That people dread to be known as former patients of sanatoriums is evident from the fact that it is difficult, if not impossible, to form an organization of "alumni" of sanatorium graduates. Some with whom I spoke on this subject told me candidly that they feel grateful for all that has been done for them in the institution, but they want to forget it. They point out that the fact that one has been a patient and cured of tuberculosis in a sanatorium is not a recommendation under present conditions. It does not help in getting a job or in retaining it; it is not of material assistance in contracting matrimony, especially for women.

Several years ago I was consulted by a workman who some three weeks prior to his visit to my office, while at work, expectorated some blood. He at once consulted the physicians in one of our tuberculosis clinics and they, evidently guided by the principle that all hemoptysis is to be considered of tuberculous origin, unless due to some other cause which is ascertained at the time of the examination, pronounced him tuberculous. On the day he consulted me there was a recurrence of hemoptysis. A careful physical exploration of the chest failed to reveal any signs of a tuberculous lesion, but inspection of the throat showed distinctly that the bleeding came from varices in the pharynx.

Reassured, the patient returned to work, but found that his employer refused to have a consumptive in his factory. But when he brought him a letter from me to the effect that he was not a dangerous consumptive the employer permitted my patient to resume work. And then only his troubles began. The workmen in the factory who witnessed the first attack of hemoptysis, and had read about the great dangers of transmission of tuberculosis, refused to work with a consumptive and threatened to strike if the menacing individual was not removed. Arguments on the part of the employer were of no avail—only a certificate from the health department, the workmen stated, would convince them. This my patient could not obtain because the physicians at the clinic had not finished their observations, which consisted in all conceivable examinations frequently repeated, but they evidently omitted to look into his throat on the day he was bleeding, in all probability because this was the province of the laryngologist of the clinic, and this specialist came only on some stated day. Perhaps on the day the laryngologist examined this patient the source of the hemorrhage was not visible. At any rate, my patient had to look for another job.

What is to be done in doubtful cases? While I do not claim that my method is the best, yet it seems to me that under present conditions it is the least harmful. In doubtful cases the patient is placed under observation after he is informed that while he presents no definite symptoms or signs of tuberculosis yet there is a lurking suspicion, and he must be carefully watched for several weeks. Some are told that while they are not tuberculous, they are threatened with the disease and unless they take extreme care of themselves they are likely to develop the disease. If there is no fever, tachycardia, emaciation, debility, etc., it is advisable to permit the patient to continue at his avocation while he is under observation, because some cases of incipient tuberculosis temporarily improve during the first few weeks of rest and thus a false sense of security may be gained, as after the administration of opium in cases of appendicitis. If observation shows that the temperature rises to some degree during the afternoon, perhaps a subnormal temperature during the early morning hours on rising, that the cough persists, that there is loss in weight, etc., physical signs will surely make their appearance in the chest, permitting the localization of the lesion in the lung.

In active and progressive cases it will not be very long before these phenomena will clear up the diagnosis. If these symptoms persist but no definite physical signs can be elicited in the chest, the prognosis is gloomy indeed and there is very little to lose by waiting. With but exceedingly few exceptions the more active, progressive or acute the process the sooner the diagnosis will be made, although we are able to save the patient only on exceedingly rare occasions in these acute cases. The more sluggish cases may not reveal themselves by definite physical signs for quite some time. But you lose nothing because the disease does not progress quickly in these cases and the resistance of the patient is good.

It is a fact which is but rarely considered that in the chronic cases, which are the majority of those we have to deal with, the period of active disease was nearly always preceded by several attacks of tuberculosis which were aborted, the patient

restrictions of a practical insurance examination; the rating of the group is "prognosis," and given data on a sufficient number of cases over a long enough exposure from which a reliable calculation can be made—it becomes primarily an actuarial problem.

In a study such as this, we must keep these two elements—medical diagnosis and actuarial prognosis—clearly in mind.

I have had the advantage, in preparing this paper, of the collaboration of my colleague, Mr. H. W. Allstrom, associate member of the Actuarial Society. Our records were taken purposely from different clinics, from different sections of the country, so as to attempt a fair average of cases which receive the best clinical and surgical advice and treatment.

The group of cases represented by these clinics has had the benefit of the best advice and the best treatment, if any treatment was permitted, so that in one sense they are a select group, but on the other hand, they are in great part the more serious and more chronic cases. Undoubtedly many cases of peptic ulcer recover without special treatment, or under the care of the regular family physician, the majority never being differentiated from "indigestion" or "gastralgia." Our groups are, however, probably fairly representative of cases which are definitely diagnosed as ulcer.

As stated, our records obtained from clinical cases undoubtedly represent a more serious group of peptic ulcers—that is, those requiring radical treatment. Records of policy-holders with a history of peptic ulcer would, on the other hand, show a very select group, and if a group of ulcer cases had been shown in the Medico-Actuarial investigation, an approximately fair rating would lie somewhat between this percentage and ours.

We shall show the actual tables resulting from our investigation, and then venture to modify their indications into what appears to us to be the most reasonable interpretation possible with the available data.

We cannot here give more than passing notice to the etiology, pathology, or treatment of peptic ulcer, except as the latter may influence the prognosis.

Rosenow's recent work demonstrating the streptococcus as the characteristic bacterial finding in old ulcer, is most suggestive of the condition being an infective process, and that in the treatment of these cases it is highly important to locate and eradicate the original site of infection, inspecting the tonsils, teeth, appendix, gall bladder, etc., just as to-day we would not simply treat rheumatic fever as an arthritis.

Such a very large proportion of ulcer cases give a long history of dyspepsia and indigestion antedating the more presumptive symptoms of ulcer, that it is at least possible that the infection ordinarily takes place in conditions leading to chronic gastric stasis and irritation of the mucous membrane. Here, however, we must also bear in mind that true ulcer may only give symptoms of indigestion, gas, discomfort, etc., over long periods, or may even be entirely latent.

A number of cases are associated with chronic appendicitis and chronic cholecystitis which may act as a causative factor both by furnishing a spot of infection and also by causing more or less chronic gastric disturbance and stasis. Any other condition associated with lowered resistance, such as anemia, neurosis, etc., may furnish the predisposing factor,

and when any source of infection exists the peptic ulcer may result. Once established, the constant bath of acid gastric secretion tends to prevent healing.

Treatment concerns us here only as affecting a subsequent ruling, and yet the present status of treatment of peptic ulcer is so strikingly divided among the highest authorities that perhaps in no other condition is there such direct conflict between medical and surgical treatment. Sippy in this country, and Boas abroad, represent the extreme of confidence in medical treatment. Sippy confidently believes that a very large majority of cases, even with considerable chronic obstruction, can be cured by neutralizing the gastric acidity, and proper diet, and Boas goes so far as to state that all symptoms are relieved in fourteen to eighteen days under suitable treatment, and that he never has occasion to use operative measures for uncomplicated chronic ulcer except in rarest cases.

The surgical point of view is voiced by Mayo when he says he can see little difference between the medical cures and the usual abatement of active symptoms, which is one of the periodic and characteristic symptoms of peptic ulcer.

There is no question that some cases of peptic ulcer recover without operative interference, but I have seen no evidence based on the subsequent history of a sufficient number of medical cases over a period of five to ten years which would justify the optimism in regard to a permanent cure by medical and dietetic treatment in so large a proportion of cases as claimed by some. On the other hand, our cases do show conclusively that surgical treatment does cure for five years and more a considerable proportion of serious cases of peptic ulcer when dietetic and medical treatment over a long period of years has failed. Our cases show cured and improved, 77 per cent. Graham's figures for the Mayo Clinic experience are 67 per cent. cured, 19 per cent. much improved. As Dr. Barker of Johns Hopkins Hospital says: "The question of therapy is still open; medical men and surgeons must continue to work together on this problem until the interchange of opinion and experience bring us at length a conclusion."

This conclusion will no doubt be a compromise between the two views, developing a more definite demarcation between cases suitable for medical and surgical treatment, unless some specific treatment or operation should be devised which will offer more positive results than are obtained at present. Dr. Mayo voices the best course open to-day when he says that those patients who can recover under medical treatment should be given a chance to do so. . . . "but that if permanent cure does not take place within a reasonable period, the patient should have surgical treatment."

The results of treatment in our cases are indicated by the following tables:

TABLE I. RESULTS OF LATEST INVESTIGATION									
	Excisions and Polypectomies		Gastro-enterostomies		Other Operations		Medical Treatment		No Treatment
	No.	%	No.	%	No.	%	No.	%	No.
Recovered.	144	53	349	62	6	32	27	33	10
Improved.	47	18	92	16	6	32	23	28	7
Unimproved..	52	19	78	14	4	21	19	24	1
Dead	28	10	44	8	3	16	12	15	4
Total.....	271		563		19		81		22

The foregoing table includes all those cases upon which subsequent information was secured. It does not include those which died within three weeks of operation or those of which nothing was learned after operation or treatment.

The following table gives a similar comparison, but only on those cases upon which the latest information was received more than three years after operation or termination of hospital treatment:

TABLE II.

	Excisions and Pyloroplasties		Gastro-enterostomies		Other Operations		Medical Treatment		No Treatment

Total.....	131		219				27			

In deciding whether a given applicant should be classed under peptic ulcer, we have, first, the frank admission of "ulcer" in the examination, which was formerly rare, but with better general diagnostic methods is becoming more frequent; second, the cases from which ulcer may be suspected from the given history or examination; third, the cases in which it may be suspected from supplementary information obtained from the examiner.

A history of recurrent or persistent dyspepsia accompanied by epigastric pain, is highly suggestive of gall-bladder disease or peptic ulcer, particularly the latter, if the pain is related to the taking of food. The more characteristic pain of stomach ulcer is soon after taking food; of duodenal ulcer, before meals, at the height of digestion and of acidity, or when stomach is emptying.

Few blanks that I have seen inquire specifically for a history of peptic ulcer. It would seem from the seriousness of the condition and the increasing frequency with which it is recognized and treated, that the time has come to include this question in the blank, if different specific diseases are asked for. In those blanks which cover all diseases under the general terms of cardiovascular, nervous, gastrointestinal, etc., sufficient confidence is placed in the local examiner to expect him to elaborate these questions to the applicant, and the general question of gastrointestinal disease would have to suffice.

In view of the comparatively recent recognition of the frequency of gastric ulcer, the suggestion that companies should give their examiners some advice on looking more closely for organic disease of the stomach is timely. "Indigestion" corresponds in the general practitioner's nomenclature in relation to gastric ulcer, about as chronic bronchitis did in relation to phthisis twenty years ago. Where examiners report indigestion, dyspepsia, abdominal pain—we are, of course, accustomed to write back for more definite advice with particular reference to appendicitis, renal or hepatic colic. We should unquestionably add inquiries aimed at eliciting evidence of peptic ulcer; that is, location of pain and radiation, evidence of localized tenderness, relation of pain to meals, if vomiting, if hematemesis.

There is considerable value to a definite question in the blank naming the specific disease. It certainly calls the examiner's attention to its possibility, and he is more likely to elicit pertinent information by his questioning and his examination.

It is most important in obtaining a history of

"indigestion" to ascertain whether the condition has recurred, the intervals of recurrence, and the months or years the condition has persisted. In considering a case of recurrent indigestion with pain, we must face the mortality of chronic appendicitis, cholecystitis, and peptic ulcer, where our investigation has eliminated a toxic cause such as tuberculosis, uremia, etc.

As would be expected, our figures show that first symptoms antedate treatment for a much shorter period in the medical cases than in the surgical cases; in other words, surgical intervention is usually delayed, and in a very large proportion of cases is preceded by more or less medical treatment. Surgical "cures," therefore, are in many cases enjoyed after the failure of medical treatment.

Of the 1599 cases, 58 per cent. had symptoms for more than five years; 23 per cent., under one year; 19 per cent., between one and five years.

Divided into medical and surgical:

Surgical: 65 per cent. had symptoms for more than five years.

11 per cent., one year or less.

24 per cent., between one and five years.

Medical: 34 per cent. had symptoms more than five years.

33 per cent., within one year.

33 per cent., between one and five years.

The practically universal symptom is indigestion, or indigestion and pain; 26 per cent. had indigestion, or indigestion and pain, without vomiting or blood; 41 per cent. had vomiting; 23 per cent. had vomiting of blood.

Of those cases giving first symptoms more than five years prior to the treatment under consideration, 20 per cent. had indigestion only, previous to the five-year period; 48 per cent. had pain; 27 per cent., vomiting; 5 per cent., blood.

Indigestion and pain is most frequently the earliest symptom, the vomiting and hematemesis tending to develop at a late date, and vomiting of blood in a large majority of cases coming within one year of the time when radical treatment is sought. See following table:

TABLE III. PERCENTAGE OF TOTAL CASES.

	Vomiting Without Blood	With Blood
1 year prior....	16%	15%
1-2 years prior..	6	2
2-3 years prior..	3	14
3-4 years prior..	2	1
4-5 years prior..	2	1
5+ years prior..	13	3

For the purpose of computing expected mortality we eliminated those cases upon which no information had been obtained following treatment, and those which died within three weeks of treatment. The cases thus eliminated are shown in the following table:

TABLE IV.

Character of Treatment	Excisions and Pyloroplasties	Gastro-enterostomies	Other Surgical	Medical Treatment	No Hospital Treatment	Total
Total number of cases	380	763	50	345	72	1599
Died within three weeks of operation or treatment	1	39	7	26	1	74
Not heard from after operation or treatment	0	164	0	238	49	451
Balance from which subsequent information was secured	379	560	19	81	22	959

From these figures it will be noted that of a total of 1,599 cases, 86 died within three weeks following treatment—a ratio of 5.4 per cent.—surgical 5 per cent., medical 6.6 per cent. This immediate high mortality is undoubtedly due to the serious cases admitted to certain clinics, *i.e.* cases with perforation, acute hemorrhage, etc.

The favorable operative mortality of the Mayo Clinic, 1.5 per cent., would probably be more representative of the best surgical treatment of interval cases. Dr. Mayo's estimate of general operative mortality for duodenal cases is 2 per cent., with 3 per cent. to 4 per cent. for gastric cases. An immediate mortality of 2 per cent. covering all cases, medical and surgical, would probably cover an average experience on a group representative of the ordinary insurance applicant.

TABLE V.—NUMBER OF CASES ON WHICH SUBSEQUENT INFORMATION WAS RECEIVED LISTED BY YEAR OF LATEST INFORMATION

Years After Operation or Termination of Treatment	Excisions and Pyloroplasties	Gastro-enterostomies	Other Surgical	Medical Treatment	No Hospital Treatment	Total

tions and tend to gradually drop out of sight. This tendency must be taken into account as modifying the high mortality shown, with its tendency to steady increase, and is illustrated by the following table. We have allowed for this tendency in our appended suggested rulings.

We have divided the mortality by years of exposure following treatment and by method of treatment, as shown in Table VI.

We did not feel that the number of our cases justified further subdivisions by age. After the first year following operation on the cases under observation, the ratio of actual to expected mortality is not definitely affected by age—if anything, the tendency being to an increase in percentage with increase in age. On most of those cases dying within three weeks of operation, which cases are not included in our Table VI, but are shown in Table IV, the death rate, particularly at ages under 50, is not greatly affected by age, and the deaths can more properly be considered as a percentage of total operated on rather than a percentage of expected mortality. The same condition holds true to a large extent on the deaths during the first year but subsequent to three weeks after operation.

Including all surgical cases, the ratio during the first year following operation is 570 per cent., of expected on ages 39 and under, 427 per cent from ages 40 to 59, and 257 per cent. on ages 60 and over. Where we have attempted definite insurance ratings, we have to eliminate the cases of "other operations," for the reason that they represent a poorer type of risk than will usually be found in insurance risks,

In estimating the mortality on successive periods following treatment, we must bear in mind that those cases which report subsequent history in reply to inquiry, will probably be the more unfavorable cases, and this tendency will increase directly with the length of the interval after treatment. That is, the well patients tire of answering the routine ques-

being mostly exploration for perforations, many patients being moribund on admission. Considering, therefore, strictly the gastroenterostomy, the excision and the pyloroplasties, the mortality in the first year was 582 per cent. on ages 39 and under, 413 per cent. on ages 40 to 59, and 203 per cent. on ages 60 and above.

Analyzing our figures with reference to severity of prior symptoms, we find that the mortality on cases without vomiting or hematemesis prior to the treatment under consideration, proved much more favorable than those which had either simple vomiting or vomiting of blood. This would be naturally expected on ages 39 and under, 427 per cent. from resent the later cases, after obstruction and stasis had developed. For example, gastroenterostomies on cases without vomiting or hematemesis gave practically a normal mortality after the lapse of one

year—a ratio of three deaths to 3.21 expected. Excisions and pyloroplasties showed two deaths to 1.06 expected; medical treatment, three deaths to 1.01 expected.

Although the number of cases is too small for positive conclusion, the relation between the three divisions of treatment is similar to results in Table VI, and the ratio of actual to expected deaths is less than the total group shown in Table VI.

In order to give our work a more concrete value, we have ventured to suggest some rulings for different groups, which might be broadly deduced from our figures and from a free interpretation of them,—attempting to co-ordinate the percentages found with the results of general clinical observation. We appreciate that these rulings must be purely tentative, and we submit them with the idea that they may induce free discussion, and with the knowledge that they will be modified by subsequent data and by the individual judgment of anyone who may care to use them as a guide to action.

We think it advisable, in cases with surgical treatment, to limit consideration for any form of policy to cases that had been without serious active symptoms for one year, such as hematemesis, vomiting, severe pain, etc.

We have then divided other surgical cases as follows:

First: After gastroenterostomy where there has been no previous vomiting or hematemesis—accept standard after three years, providing there were no subsequent symptoms—between one and three years, rate 135 per cent. to 150 per cent.

Second: After gastroenterostomy, where vomiting or hematemesis had appeared in prior history—refuse for standard for at least five years,—acceptable on rating for excess mortality of 150 per cent. to 175 per cent.

Third: After excision and pyloroplasty, proving

more unfavorable than after gastroenterostomy—we would suggest rating of 140 per cent. plus when no previous vomiting or hematemesis—increasing to 200 per cent. plus when there has been vomiting or hematemesis.

Since the original draft of this paper was completed, a paper by Drs. Finney and Friedenwald has appeared (*American Journal of the Medical Sciences*, October, 1915) in which decided preference is expressed for pyloroplasty over gastroenterostomy, so that this point must still be held *sub judice*. When it is a choice between two methods of operation, the results will always be markedly influenced by the skill and familiarity of the operator in the particular operation of his choice. For example, when the difference in results is not great, a surgeon who performs pyloroplasty and has a large experience with a certain technique would get better results than with gastroenterostomy; whereas a surgeon who preferred gastroenterostomy might obtain the opposite results. The personal equation can never be left sight of in considering any medical question.

Such is the character of operative procedure required for the radical cure of peptic ulcer that in this condition, particularly, the experience and skill of the surgeon will be an important factor in determining end results. Our figures and deductions would hold only where skilled operative procedure has been employed.

After medical treatment: In attempting to rate a case of peptic ulcer which has had any active symptoms within two years, particularly if vomiting or hematemesis—we feel that the possibility of operative interference with its immediate mortality must be allowed for, and that it could perhaps be more properly covered by an extra charge than by rating up in age.

The direct operative mortality we have estimated

at 2 per cent., and 3 per cent. for the first year following operation, or a total of 5 per cent. This, including a good loading for possible fluctuation, would make the extra charge at least double that which we have been accustomed to add for recent attack of appendicitis without operation.

For the purpose of covering this immediate excess mortality, it would be most desirable to collect the entire extra premium the first year, but from a practical standpoint of being able to place the policy on a basis satisfactory to the applicant, it is necessary to distribute the charge for a few years.

In the appendix cases we have been charging \$10 extra the first year, this extra decreasing 20 per cent. for the next five years. In the ulcer cases, the extra would, of course vary with the severity of symptoms and interval since the last active symptoms.

In considering cases that have been free from symptoms after medical treatment or without special treatment for more than two years, we feel that they may be rated from 175 per cent. to 250 per cent. dependent upon severity of symptoms, particularly upon history of vomiting or hematemesis. Of course the two-year period allowed for possible operative mortality in these cases is largely arbitrary, and the choice of a flat extra or a rating up in age will be determined by individual judgment or special features of the case. From fifth to tenth year after active symptoms, these cases may be rated at 150 per cent. plus minus, and after ten years, may be accepted as standard.

CHANGING A FALSETTO VOICE TO A BARITONE.

BY FRANK J. O'DONALLOK, M.D.

NEW YORK.

STANTON, N.Y., 1915.

JOHN E., 35, telegrapher, came to consult me for some slight illness. In speaking he used the falsetto voice and never had spoken in the normal register. Before dismissing him, in connection with the illness for which he came, I advised him to go to some elocution or singing teacher to learn to speak in his normal voice. The patient said he had not supposed that anything could be done to change his voice,

but he would be glad to go to such a teacher and would take my advice.

It occurred to me later that I would like to try the experiment myself, so I sent for him, and he came in due time. I took him to the piano. All I know about the piano is thumb exercises, but I found that he knew less, for he could not carry a tune correctly, nor even a single note. He was consistently sharp or flat. His musical ear was decidedly defective. As I sounded various notes in the scale, he sang them in the falsetto, although this was difficult because of his defective ear. I brought him down in the descending scale as far as his voice would go, and then I sounded the next lower note. He promptly sang some note in the upper scale, any note, all in the falsetto. I tried the experiment several times, always with the same result. I sat quite puzzled and beaten. I had not the least idea, in these circumstances, how I was to proceed with a case like this, and doubted if it would be possible to make any progress at all with him.

Suddenly an idea came to me, and I asked him to clear his throat and made him repeat this several times while I listened carefully. In that noise of clearing his throat, I heard the man's natural voice, or thought I did, the suggestion of it, enough to begin on. I requested him to cough and clear his throat again and again. The natural voice was evident to me at the very end of the coughing noise. I asked him to notice that as he cleared his throat, the sound naturally separated into something like two parts, the cough and a noise which followed it. (It might be represented, though not correctly, by the word "a-hem.") I perceived that I might use this reaction to the cough, as it might be called, the second part, the sort of rebound, if I could get hold of it. All I had to do then was to get him to prolong the second sound. I made him repeat the exercise and, little by little, got him to accentuate this second part of the cough. Then I asked him to divide this cough-clearing process, consciously, into two parts, much as if he were to say "a-hem." He learned to do this, though it was difficult for him, as he often broke into the falsetto. In this way he finally produced out of this second sound a good full tone in the normal register. All this took me about an hour, and I was satisfied that I had struck a method by which to bring out his natural voice.

In speaking he still lapsed into the falsetto, of course; up to this time in his life he had never used the slightest suggestion of the normal voice, it was fixed in the falsetto. I saw him again on the following day, and although he was able to produce the normal register tone, when carefully guided to it, the voice would still break often, and whenever he spoke it was in the falsetto. I practised with him, going from one note to another until he got a range of an octave in the normal register. That was all I needed for practical purposes. His voice became more and more free. He said that the voice sounded strange to him and was quite in doubt as to whether it was not an artificial voice that I had produced. I continued to work with him, developing this tone and got him to speak by first singing a simple word, then speaking it in a singing tone. From one word, I easily got a few more out of him. The voice still broke occasionally, but it was a simple matter now to keep it fairly steady in the normal. I gave him some simple exercises with simple phrases, such as "good morning," "hello, Charley,"

"wake up," "how's the parrot today?" and such nonsense, spoken on a full breath and in a "bold, bad man" sort of way. I told him to practise a little at the piano at home the exercises I had done with him and also the exercises in speaking, to blurt the phrases out to anyone who happened to be near him. And he did it.

On the fourth day I picked up a volume of Longfellow and asked him to read three or four verses. He did it without a break, and so well that I fetched in a lady who happened to be in the house at the time and who was well acquainted with the patient. I seated her comfortably in an armchair and put him through his little stunt. She was utterly astonished! I saw him every day for about a week, and then less and less often. His normal voice was thoroughly established, a good manly baritone. He telephoned to everyone he knew within a hundred miles so that they might hear his new voice. He was not sure for a considerable time that it would last. One day, however, a couple of months from the time I began with him, I asked him to speak again in the old way. He was unable to utter a sound in the falsetto; he had forgotten how. This seemed to me fairly stupid, but he could not do it.

This happened some years ago. I never reported the case because I imagined such cases must be well enough known to the specialists, and it did not seem to me that it would be of particular interest. Recently, however, I had occasion to speak of the case in the presence of several physicians, one of whom was afflicted in the same way. I related the case for his benefit. As he seemed interested, I told him I would like to try and straighten him out if he cared to have me to do so. A reputable older physician, connected with one of New York's leading hospitals, who was present, expressed the opinion that such cases are structurally defective and incurable. I never saw the young doctor again, and he may or may not have taken this man's word for it, but this case was enough like that of "J. E." to warrant me in supposing that his voice could also have been restored in a similar way.

The incident made me think the case of "J. E." worth reporting.

110 WEST EIGHTIETH STREET

Miscellany.

Duration of Smallpox Immunity After Successful Vaccination.—Dr. William H. Park of the Research Laboratory of the Department of Health has recently reported the results of investigations into the duration of smallpox immunity conferred by successful vaccination. This may be determined in two ways: (1) by observation of those who after being successfully vaccinated are exposed to smallpox, and (2) observing the duration of immunity to vaccination with vaccine virus. Although the inspectors of the Department of Health occasionally meet with persons who can be revaccinated successfully at the end of six months, investigations have shown that 14 to 28 per cent. of persons are susceptible to revaccination at the end of one year, 50 per cent. at the end of five years, and 85 to 89 per cent. at the end of ten years. When vaccine of high potency is used 99.9 per cent. of persons who have never been vaccinated previously will "take." Vaccinated persons are susceptible to revaccination before they lose their immunity to smallpox, as the rubbing in of vaccine virus is a

much more direct inoculation than the breathing in of the infected air. The experience in this country during three years, as to the time after vaccination that smallpox has developed in those previously successfully vaccinated may be taken as a reliable indication of the length of the immunity. Statistics issued by the United States Public Health Service, for three years ending last June, show that in 6,312 cases of smallpox which were carefully investigated, only 79 patients had been vaccinated within seven years preceding the attack, while 3,386 had had their last vaccination more than seven years previously, and 2,839 had never been vaccinated. In 18,953 cases reported to the public health authorities, but not investigated, 798 were said to have been vaccinated within seven years, and 1,632 more than seven years preceding the attack, while 16,523 had never been successfully vaccinated.

The shortest period of immunity which has been conferred by vaccination in the experience of the Department of Health is nine months, but in the literature three cases have been reported of even shorter duration, one of one and a half months, one of four months, and one of six months. Dr. Park states that while it is well known that an occasional individual responds only slightly to immunizing agents, this lack of response is, fortunately, in the case of smallpox vaccination, never absolute, although the degree of immunity established varies with the individual. The mass of statistics now available on this subject indicates that it is wise for anyone exposed to smallpox to be vaccinated, if a successful vaccination has not been obtained within nine months. The general population should be vaccinated about every five years when smallpox is at all prevalent, and even when the disease is absent it is necessary that all persons be vaccinated in infancy and again in childhood so as to keep the population moderately immune.

Available Radium Sources.—A subject of extreme interest is the possibility that the reserves of radium in Nature are very limited in amount. Recently several investigations have been made with this end in view. Naturally only paying ores are considered. Deposits of this sort are to be found at Joachimsthal, Cornwall in England, Portugal, Australia, and especially in Colorado and Utah. At a session last summer of the Niederrheinische Gesellschaft f. Natur- und Heilkunde of Bonn Steinmann stated that this "visible" supply of radium was about 400 grams, of which only one-fifth or 80 grams was fully available. We have actually in use 12 grams, while the annual production at the present time is between 4 and 5 grams. To supply properly all the leading medical centers we need 60 grams.

Anthropological Studies.—We referred recently to the anthropological researches made by Buschan of the German medical staff on the prisoners of many races in German hands and also many of the young soldiers. Austria has now followed suit and Dr. Pösch, professor of anthropology and ethnography at the University of Vienna, has been ordered by his Government to conduct anthropological measurements among the prisoners of war under Austrian control. Measurements will be taken of the length and breadth of skulls, chests, and cheeks; the shades of color of hair and eyes will be tabulated, and in the case of prisoners of little known nations vocabularies will be collected.

MEDICAL RECORD.

New York, January 22, 1916.

ANNUAL REPORT OF THE UNITED STATES PUBLIC HEALTH SERVICE.

THE report of the Surgeon-General of the Public Health Service has just been published and is from all points of view a most satisfactory document. It provides a record of the largest amount of work performed by that very capable body and supplies yet another proof of the extreme value of the service rendered to the public by its individual members. Since the passage of the law of 1912 the functions of the Public Health Service have been materially broadened, thus greatly increasing its powers for good and its usefulness to the American people. Administrative supervision of the work of the Service is conducted through seven divisions, and operations for the fiscal year are reported under the titles of the divisions as follows: 1, Scientific research; 2, Foreign and insular quarantine and immigration; 3, Interstate quarantine; 4, Sanitary reports and statistics; 5, Marine hospitals and relief; 6, Personnel and accounts; 7, Miscellaneous.

Among the most important studies carried on during the year under review have been those dealing with pellagra. These all seem to point to the view that pellagra is a diet disease, a "mal de misère." In order to determine whether it is a deficiency disease, extracts of certain foods rich in so-called vitamins were prepared in large quantities at the Hygienic Laboratory in Washington. These extracts were then administered to patients and their therapeutic action was noted. The results obtained will be reported in the near future. The metabolism of pellagrins was also subjected to an intensive study. A new method for the quantitative estimation of gastric pepsin has proved of great value in the study of gastric functions in cases of pellagra. It was found that in almost all severe cases digestion was greatly reduced and pepsin and free hydrochloric acid were usually absent. The study of urinary indican revealed the fact that this product of intestinal putrefaction may be entirely absent in marked cases of pellagra, provided that the patient consumes a mainly vegetable diet. On the other hand, a diet rich in animal protein leads to a marked increase in the excretion of indican. It seems, therefore, that no relation exists between intestinal putrefaction and the intensity of the disease,

so far as can be ascertained by the study of indican excretion. The absorption of food from the intestines seems to be normal in pellagra, except in cases with excessive diarrhea. The study of the protein metabolism in pellagra has thus far not revealed any abnormality. The other phases of metabolism are under investigation. It may then be stated that the final experiments which have only just been published have led to the conclusion that pellagra is a deprivation disease resulting from a faulty diet containing an excess of carbohydrates. This conclusion has been reached as the culmination of investigations extending over a period of seven years.

The crusade against malaria has been continued with much success. Surveys of breeding places of Anopheles, together with a study of the geographical and climatic, social, hygienic, and economic conditions, and the prophylactic measures best applicable for the control of malaria, were made in 34 selected localities. These surveys have been of great value in the study of the life and habits of anopheline mosquitos, and the measures recommended for the abatement of mosquito breeding places, when carried out, have resulted in a great reduction in the incidence of malaria.

The antitrachoma campaign during the past year has been actively conducted by Surgeon John McMullen. The experience gained thereby has further demonstrated that the method adopted by the service of establishing small ophthalmological and public health hospitals in the communities where the disease is known to exist presents the best solution of the trachoma problem. It serves the several purposes of curing the existing cases and of furnishing bases for the district work and a means of furthering education. The very gratifying results accomplished in both eradication and prevention through these hospitals has justified the enlargement of the fields of operation and the extension of the work to other States.

When plague broke out in New Orleans the State and local health authorities requested the Public Health Service to take charge of the situation. Extensive rat-proofing and other antiplague measures were put into effect with the result that the disease was eradicated from among human beings and the rodent infection was practically exterminated. Studies of occupational diseases and industrial hygiene have occupied the attention of the service at many places during the year. A survey of the industries of Cincinnati was made to determine the cause of the prevalence of tuberculosis among industrial workers. The investigations relating to the migration of persons suffering from tuberculosis were completed. Upon the request of the health authorities of five States, the organization and operations of the respective boards of health were studied and recommendations advanced for the improvement in the powers and duties of these bodies. The health organizations of several cities were likewise investigated.

During the year the service has continued its systematic studies of typhoid fever. This has taken the form of epidemiological surveys of local outbreaks when requested by the State authorities,

advice in improving local methods of sewage disposal, object lessons in prevention, typhoid vaccination of Government employees and beneficiaries of the service, and educational lectures, bulletins, press notices, etc. Rural sanitation work was carried on in six different States and everywhere resulted in the reduction of typhoid and other communicable diseases.

Public health laboratories for the prevention of the interstate spread of disease were established at Chicago, Seattle, and numerous other railway centers. Additional duties have been placed upon the service by the extension of relief benefits to the newly organized Coast Guard and the physical examination of seamen applying for the rating of "able seamen." For this reason, and because of the greatly increased health functions of the service an increase in the commissioned personnel is recommended.

It would be superfluous to praise the work of the Public Health Service. It will suffice to say that its high standard of efficiency has been well maintained during the past year and that judging from results it must be regarded as one of the main health assets of the country.

MEDICO-MILITARY ASPECTS OF THE EUROPEAN WAR.

It goes without saying that when the European war first broke out the organization of the German armies was superior, by far, in all respects to that of the armies of the Allies and of course this remark applies with equal force to the medico-military service of the contending armies. However, time has to a great extent remedied this state of affairs, and now, at any rate so far as the French and British medico-military services are concerned, there are few points in which the Germans can boast of a superior organization. Recently, a most instructive book has been published being a "Report on the Medico-Military Aspects of the European War from Observations Taken Behind the Allied Armies in France," by Surgeon A. M. Fauntleroy, U. S. Navy. The book in question is most illuminative and provides an excellent "bird's eye view," if the term is allowable, of the medico-military situation in the allied armies in France.

It would be impossible within the limits of this notice to consider even briefly the various phases of the subject dealt with by the author. With regard, however, to the prophylactic treatment of the septicemic grade of wound infection it is of interest to quote the following statements: "The prophylactic procedures would seem to resolve themselves into the precautions which are more or less familiar to all, and which are the usual precautions against wound infection. Under the present circumstances of trench warfare in Europe, it would seem to be well-nigh impossible to obviate an exceedingly high percentage of wound infection, and especially infection with the organism responsible for the progressive emphysematous necrosis. The reasons for this are not far to find. In the first place the entire western European war area has

undergone for many years an intensive process of cultivation which has resulted in the soil being saturated with fertilizers and caused it to be the medium par excellence for harboring the infective organism. Once the trenches are dug deep in this soil, there is no escape from the ever-present conditions which are favorable for infecting every wound. Soldiers are obliged to occupy these trenches for days and nights consecutively under all weather conditions, so that their clothing and body surface become more or less permeated with the trench dust and dirt, which, of course, contains the infective organism in great numbers."

Consequently, the author thinks that a consideration of these facts must lead to the theoretical conclusion that something might be accomplished in a prophylactic way by not only covering the floor of the trench with small fagots of wood, which is now the universal custom, but by making an effort to disinfect the sides of the trench. As said before, however, it would be useless to endeavor to consider the book in detail, and it must suffice to say that it is well worth a careful study. The illustrations are not the least attractive part of the book.

CARCINOMA OF THE MALE BREAST.

As is generally understood, this neoplasm has but slight connection with typical cancer of the female breast, being of very exceptional occurrence despite the fact that it occurs in a superfluous structure. It bears some resemblance to the scirrhus or atrophic form of cancer of the female breast in that it occurs in senile subjects, grows slowly, attains but limited size, and tends from the first to involve the lymph node packet in the neighboring axilla. That so rare yet typical a growth can occur in a highly atypical form is shown by a case described by Husse in the *Muenchener medizinische Wochenschrift* of November 9. The man was but 43 years old, a consumptive, and had besides a mitral lesion of unknown duration and origin. Two months before consultation a small tumor was noted in the left breast. This grew with amazing rapidity and both macroscopically and microscopically appeared to be a medullary cancer. The lymph nodes in the axilla already formed a packet the size of an English walnut. The patient submitted to a very radical type of removal without ill consequence. The case is singular in many respects. Florid cancer in any location is not prone to attack a man with health impaired by cardiopulmonic disease, and it is of course a mystery why it should have selected so rare a site. Since it was the left lung alone which was involved as well as the left heart, one is inclined to wonder whether frequent percussion close by or over the cancer area could have by a succession of petty traumatisms furnished the necessary determining factor. The author is entirely silent on this possibility, perhaps because it was difficult to secure a good personal history.

VON NOORDEN ON HIGH PROTEIN DIETARIES.

In discussing a paper on blood as food read by Blum at Frankfurt last May (*Muenchener medizinische Wochenschrift*, October 19), von Noorden

stated that the longer he lived the more firmly he believed in a high protein regimen. Experiments with low protein simply show what man can do if he must. He deprecates present day efforts to ascribe all evil to high protein diet. If we choose the low protein regimen future generations will be weaklings. The physiological protein minimum is a fad (Modethorheit). Hence we must—especially when meat foods are high—make an economic use of such products as blood, naturally in the form of sausages (blood pudding, blood and tongue sausage, etc., etc.). Blood is even medicinal as a carrier of organic iron. Blood powder and the like may also be used for reinforcing other dishes, such as soups, with protein. As far back as 1893 the author tested subjects on a bread and butter and potato diet by adding increasing quantities of blood, using as controls eggs and cheese and meats. Up to a certain point the utilization of blood was excellent. The blood serum is doubtless readily utilized while the reverse may be the case with the hematin which appears to increase the indican and other sulphuric acids in the urine. The subject should be studied anew, von Noorden holds.

WARFARE AGAINST DIPHTHERIA IN GREATER BERLIN.

THE presence of the great war does not appear to interrupt in any way the warfare against contagious diseases in the German metropolis. Ritter, in a brief communication to the *Berliner klinische Wochenschrift* for November 1, claims that the typical form of the disease, appearing rapidly in epidemic incidence presents no problem at all. It permits of ready recognition, prompt isolation and immunization, and low mortality. A certain bacteriological diagnosis requires but 16 hours, and the telephone and special messengers for carrying swabs are great time savers. A problem arises when nasal diphtheria of a subacute course arises among young children, especially in asylums. It may present only the clinical picture of rhinitis, and cultures may be negative; especially the nonvirulent and pseudodiphtheritic bacilli may complicate the finds. But the slow course of these nasal cases gives time for animal inoculation.

News of the Week.

Deaths in New York.—During the week ending January 8 there were reported in New York City a total of 1,880 deaths, giving a death rate of 17.08, as compared with 1,714 deaths and a rate of 16.01 during the corresponding week of last year. Of these 85 deaths were due to grip, as against 10 during the same week of 1915, showing that there has undoubtedly existed a very large number of cases of the disease. Bronchitis and pneumonia caused a total of 466 deaths, as compared with 347 during the first week of 1915; heart disease and nephritis also showed an increased mortality of 34, some of these deaths in all probability being hastened by "colds" recently contracted. The statistics for the last two weeks of 1915 and the first two of 1916 show a steadily increasing mortality due to influenza, bronchitis, and lobar pneumonia, the figures being as follows: Week ending December 18: influenza, 12; bronchitis, 18; lobar pneumonia, 185; total, 215. Week ending December 25: influenza, 24; bronchitis, 36; lobar pneumonia, 251; total, 311. Week ending January 1: influenza, 74; bron-

chitis, 29; lobar pneumonia, 272; total, 375. Week ending January 8: influenza, 85; bronchitis, 29; lobar pneumonia, 293; total, 403.

Chicago Death Rate.—During the first week of this year, the total number of deaths reported in Chicago was 1,002, giving a death rate of 21.0 per 1,000, which was a slight decrease as compared with the previous week, when the deaths numbered 1,112 and the rate was 23.7, but a very large increase as compared with the corresponding week of last year, during which there were only 658 deaths, with a rate of 14.0. Pneumonia was the chief cause of death, having a fatal ending in 251 cases during the week ending January 8, and in 302 in the previous week. Influenza caused 80 deaths during the first week of this year, and 95 during the last week of 1915, while tuberculosis caused 90 and 91 deaths respectively. In the first week of 1915 only 2 deaths were ascribed to influenza. It was estimated that the number of cases of pneumonia in Chicago during the latter part of December was five times as large as during the same period of 1914.

Low Death Rate in New York State.—The New York State Department of Health in a summary of the returns of deaths in the State during 1915 gives the death rate as 15.0 per 1,000, computing it on the new estimate of population furnished by the Census Bureau. This rate is the lowest on record for the State: the total number of deaths was 145,552. The rate given by the State Department for New York City alone is 15.1, as compared with 15.0 for 1914 and 1913, and 14.9 for 1912, while for the State outside of New York City the estimated rate for 1915 is 14.9, as compared with 15.2 per 1914 and 15.8 for 1913. These figures have been protested by Commissioner Emerson of the City Department of Health, who believes that the rate for New York City, having been based on inaccurate census returns, are too high.

Hospital Acquires Property.—The New York Medical College and Hospital for Women has announced the purchase of the apartment house at 21 West 110th Street, adjoining the college property. This gives the institution a total frontage on the street of two hundred feet, and permits of a considerable extension of its plant. The purchase was made possible by the gratifying progress of the campaign for a \$200,000 building and endowment fund for the college.

A Eugenic Journal.—The Eugenical Record Office at Cold Spring Harbor, N. Y., issued this month the first number of a new publication, the *Eugenic News*, which is to serve as a medium of intercommunication between eugenists, giving besides the news of the Record Office, items of interest concerning workers in this field throughout the country.

American Journal of Orthopedic Surgery.—The American Orthopedic Association announces the appointment of Dr. Mark H. Rogers of Boston as editor of the *American Journal of Orthopedic Surgery*, which, beginning with the issue of January, 1916, will appear as a monthly instead of a quarterly. The publication office has been transferred to 126 Massachusetts Avenue, Boston.

Military Medicine.—Harvard University is about to establish in its graduate medical school a course in military medicine, which will be under the charge of Major Weston P. Chamberlain, medical corps, United States Army, who is an alumnus of the Harvard Medical School.

Typhus in Mexico.—An official statement issued in Mexico City on January 12 says that 962 new cases of typhus fever were reported during the first week of January in the city and its suburbs. This is fifty less than the number reported during the last week of December.

Case of Smallpox.—The first case of smallpox in New York City since last spring was reported to the Department of Health on January 11 from Flushing, Long Island. The patient had come from Sioux City on December 22. Inspectors from the department were immediately detailed to guard against the spread of the infection.

Open Seaside Hospital.—On January 18, the Seaside Hospital, supported by St. John's Guild at New Dorp, Staten Island, was reopened for the reception of sick and convalescent children, and announcement was made that hereafter the institution would remain open throughout the year. Detailed information concerning admission of patients may be obtained at the office of the Guild, 103 Park Avenue.

Physicians for Tuberculosis Clinics.—The Department of Health is anxious to secure physicians interested in tuberculosis work to serve as volunteer assistants in the tuberculosis clinics of the department. By a rearrangement of the salaries of the physicians attending these clinics, it has been possible to provide for a considerable increase in the salaried staff at \$300 per annum, and the volunteer assistants now in the service will shortly be promoted to the salaried staff, pending an examination by the Civil Service Commission to secure eligibles for these positions, the tuberculosis clinic physicians having only recently been placed under civil service regulations. As these temporary appointments will practically exhaust the list of volunteer assistants, the department is ready to make new appointments of volunteers, who will thus if they take the examination be eligible shortly for promotion to salaried positions. Applications should be addressed to the Bureau of Preventable Diseases, Department of Health, New York, and should in each instance state the medical college and year of graduation, and hospital or dispensary experience of the applicant.

Personals.—Dr. LEONARD G. ROWNTREE, formerly of Johns Hopkins Hospital and recently appointed dean of the medical school of the University of Minnesota, took up the work of his new office on January 10.

Dr. ROSS V. PATTERSON has been appointed visiting physician to the Philadelphia General Hospital in succession to the late Dr. Robert N. Willson, Jr.

Dr. CHARLES S. MILLER has been appointed chief of the division of vital statistics in the Philadelphia Bureau of Health.

Grip Spreaders Arrested.—The anti-spitting crusade, which was begun by the City Department of Health last week, with the assistance of the police, resulted in the arrest of several hundred of persons each day. In the Magistrates' Courts to which the offenders were summoned fines of from \$1 to \$5 were imposed in the majority of cases.

To Study Influenza and Pneumonia.—Dr. Wilmer Krusen, director of public health and charities of Philadelphia, has appointed a commission to make a study of the causes of the prevailing epidemic of influenza and pneumonia, as follows: Dr. David Riesman, chairman; Dr. Hobart A. Hare, Dr. W. Egbert Robertson, Dr. Randle C. Rosenberger, Dr. Paul A. Lewis, and Dr. John A. Kolmer.

The New York Physicians' Association.—At the next regular meeting of this association to be held at the Park Avenue Hotel on Thursday, January 27, a lecture will be delivered on "The Definite Treatment of Pneumonia" by Prof. S. Solis Cohen of Philadelphia.

Deaths of Foreign Medical Men.—Dr. BOLESŁAW WICHERKIEWICZ, Professor of Ophthalmology in the University of Cracow, has recently died in a sanatorium in Vienna of cancer of the stomach, at the age of 68 years. In addition to his great achievements as an ophthalmologist he was known as a public spirited citizen. Since the beginning of the war he had been at the head of the Red Cross organization of the Polish Legions, giving to the work his entire time.

Dr. GUIDO BACCELLI, for many years Professor of Medicine at the University of Rome, died on January 10 at the age of 84 years. He was one of Italy's leading physicians and citizens, having been a Senator in the Italian Parliament as well as Professor in the University. He was a Latinist of repute, a brilliant orator, an acute diagnostician and clinician, a good writer and a clear thinker. He was editor and one of the founders of *Il Policlino* and was President of the International Medical Congress in Rome in 1894. Among his notable achievements was the advocacy of carbolic injection in the treatment of tetanus, a therapeutic measure that has survived the introduction of anti-tetanic serum, being widely employed by army surgeons on both sides of the present war.

Bubonic Plague in Ecuador.—Health reports show that during the last year 236 cases of bubonic plague occurred in Ecuador, of which 109 ended fatally. Of yellow fever, nineteen cases were reported, eleven terminating fatally.

Baby Week.—The week from March 4 to 11, 1916, has been designated "baby week" by the Children's Bureau of the Department of Labor, and the bureau has issued a bulletin containing suggestions as to the proper observances to be held in different communities, infant welfare exhibits, follow-up campaigns, etc., together with lists of public and private organizations from which exhibit material may be borrowed. Copies of this bulletin may be obtained free of charge by application to the children's bureau.

Medical Society Elections.—NEW YORK NEUROLOGICAL SOCIETY: At the annual meeting held on January 4 the following officers were elected for the ensuing year: *President*, Dr. W. M. Leszynsky; *First Vice-President*, Dr. Frederick Tilney; *Second Vice-President*, Dr. F. Kennedy; *Corresponding Secretary*, Dr. J. Ramsay Hunt; *Recording Secretary and Treasurer*, Dr. C. E. Atwood.

KENNEBEC COUNTY (ME.) MEDICAL SOCIETY: The annual meeting of this society was held at Augusta on December 28, when the following officers were elected: *President*, Dr. H. K. Stinson, National Soldiers' Home; *Vice-President*, Dr. O. C. S. Davies, Augusta; *Treasurer*, Dr. S. E. Vosburg, Augusta; *Secretary*, Dr. S. J. Beach, Augusta.

The Late Dr. A. A. Smith.—The following minutes were adopted at a meeting of the council of the New York Academy of Medicine, held December 22, 1915: "The members of the council of the New York Academy of Medicine record with profound sorrow the death of their late associate, Dr. A. Alexander Smith. For more than fifteen years Dr. Smith was an active member of the council, rendering constant service to the best interests of

the medical profession. His energy was untiring, his judgment was of rare value, and his influence most beneficial, while his genial personality and strong Christian character made a deep and lasting impression upon all who enjoyed the privilege of his friendship. It is resolved that this record be spread upon the minutes of the council and a copy be sent to the family of Dr. Smith."—(Signed)—D. Bryson Delavan, M.D., W. Gilman Thompson, M.D.

Obituary Notes.—Dr. LEO R. NATHAN of New York, a graduate of the New York University Medical College in 1889, died at his home, on January 10, aged 61 years.

Dr. PETER HUGO ERNST of New York, a graduate of the New York University Medical College in 1886, adjunct professor of gynecology at the New York Polyclinic Medical School, attending gynecologist to the New York Polyclinic Hospital and the Demilt Dispensary, and a member of the American Medical Association and the New York State and County Medical Societies, died at his home, on January 9, aged 52 years.

Dr. GEORGE VANDER BERG ROCKWELL of Brooklyn, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1882, died recently at his home, aged 57 years.

Dr. JAMES BOWEN, formerly of Brooklyn and of Buffalo, N. Y., a graduate of the New York University Medical College in 1895, and a member of the Medical Society of the State of New York and the Erie County Medical Society, died at Saranac Lake, on January 12, aged 40 years.

Dr. CHARLES G. AM ENDE of New York, a graduate of Bellevue Hospital Medical College, New York, in 1890, and previously of the University of Jena, Germany, and a member of the American Medical Association, the New York State and County Medical Societies, and the Greater New York Medical Society, died at his home, on January 14, aged 76 years.

Dr. FENNER H. PACKHAM of Providence, R. I., a graduate of the Yale University Medical Department, New Haven, in 1866, and a member of the Rhode Island and Providence District Medical Societies, died at his home, on December 26, aged 71 years.

Dr. THOMAS JOSEPH LEAHY of Cambridge, Mass., a graduate of the Harvard University Medical School in 1892, and a member of the Massachusetts Medical Society, the Middlesex East District Medical Society, and the American Medical Association, died at his home from pneumonia, after a brief illness, on December 25, aged 46 years.

Dr. SAMUEL STILLE died of pneumonia at Atlantic City, N. J., on December 26, at the age of 86 years. He was graduated from the Pennsylvania Medical College in the class of 1857.

Dr. WILLIAM BAKER BANKS died of pneumonia at Philadelphia on December 27, at the age of 66 years. He was graduated from the Medico-Chirurgical College in the class of 1891. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. MILTON D. LICHTENWALNER died at the Homeopathic Hospital at Reading, Pa., on December 28, at the age of 69 years, as a result of injuries received a short while ago in a fall.

Dr. JESSE W. THATCHER died of pneumonia at Philadelphia on December 29, at the age of 65 years.

He was graduated from Hahnemann Medical College and Hospital in the class of 1871. He was a member of the Germantown Medical Society and of the Pennsylvania State Society of Homeopaths.

Dr. ROBERT GRAY KINNIER died at Philadelphia on December 31, at the age of 60 years. He was graduated from Jefferson Medical College in the class of 1880.

Dr. HENRY H. LOWRIE of Plainfield, N. J., a graduate of the Georgetown University School of Medicine, Washington, D. C., in 1863, died at his home on January 3, aged 75 years.

Dr. ARTHUR W. DUNNING of St. Paul, Minn., clinical professor of nervous and mental diseases in the University of Minnesota, College of Medicine and Surgery, Minneapolis, a graduate of the University of Illinois, College of Medicine, Chicago, in 1885, and a member of the American Medical Association, the Minnesota State Medical Association, and the Ramsey County Medical Society, died suddenly at his home from heart disease on December 22, aged 55 years.

Dr. JAMES MATTHEW KIERNAN of Bridgeport, Conn., a graduate of the University and Bellevue Hospital Medical College, New York, in 1908, and a member of the American Medical Association, and the Connecticut State and Hartford County Medical Societies, died at his home, from pneumonia, after a brief illness, aged 36 years.

Dr. HENRY H. ATKINSON, medical missionary at Harpoot, Eastern Turkey, died recently, from typhus fever, at Harpoot, where he had been stationed for fourteen years.

Dr. WARREN B. PALMER of Brooklyn, N. Y., a graduate of the Albany Medical College in 1880, died in the Prospect Heights Hospital, Brooklyn, from pneumonia, on January 7, aged 58 years.

Dr. JOSEPH H. TOWNSEND of New Haven, a graduate of the medical department of Yale University in 1887, secretary of the Connecticut State Board of Health since 1906, chief surgeon of the Connecticut National Guard, and a member of the American Medical Association and the Connecticut State and New Haven County Medical Societies, died at his home, from pneumonia, on January 7, aged 53 years.

Dr. EDGAR REEVE BRYANT of San Francisco, a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1889, chief surgeon of the homeopathic division of the City and County Hospital, a member of the California State Homeopathic Medical Society, and professor of surgery in the Hahnemann Medical College of the Pacific, died at the Lane Hospital on December 30, from injuries received in a fall on the grounds of the Exposition while watching the illumination on the closing night.

Dr. JOHN G. DEARBORN of Boston, Mass., a graduate of the New York University Medical College in 1858, assistant surgeon in the United States Navy during the Civil War, from 1869 to 1872 surgeon of the State Prison in Charlestown, and a member of the Massachusetts Medical Society, died at his home, after a short illness, from pneumonia, on January 4, aged 80 years.

Dr. ALONZO P. CHARLTON died of heart disease at Philadelphia, on January 12, at the age of 57 years. He was graduated from Jefferson Medical College in the class of 1880. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Correspondence.

DESTRUCTION OF THE GONOCOCCUS BY HEAT.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I was interested in reading an editorial in the January 1 number of the MEDICAL RECORD on "The Fever Therapy of Gonorrhea." I fully agree with what you say as to the destructibility of the gonococci by a prolonged exposure to temperatures of about 108° Fahr., but not when you say "ordinary hot air and diathermy seem to exert no decided action on the disease, probably because the entire blood mass should be heated at once." Dr. Weiss' experiments are most interesting, and from my own clinical experience I can corroborate all that he has proven in his experiments. In several cases of gonorrhea an attack of typhoid fever has promptly cured the disease. I have seen a case of tuberculosis of the breast with extensive ulceration promptly get well after a prolonged severe attack of erysipelas with a very high temperature. I have seen one undoubted case of pulmonary tuberculosis recover and remain well for at least five years after a long siege of typhoid fever. I have given much study to find some method which would enable us to raise the temperature of the body safely and at will, for I have long believed that fever was Nature's method of checking the growth and destroying pathogenic bacteria. My efforts in this direction have, however, not been successful.

But what I started out to refer to particularly was your statement as to diathermy exerting no decided action on the gonococci. In an article which appeared in the MEDICAL RECORD, February 12, 1912, I stated that the urethra will stand a temperature of 120° Fahr. without injury to the tissues. That a bougie heated to a temperature of 120° Fahr. and held steadily at that temperature in the urethra will raise the temperature of the skin along the side to 104° or 106° Fahr. I have proven this many times. Since this is true, certainly all the blood and all the intervening tissues are subjected to a steady heat of considerably over 104° Fahr.; probably nearer 110° Fahr.; the urethra certainly to a temperature above 115° Fahr. That such an application of heat does exert a decided action upon the gonococci I have proven many times and any one else may prove the same if he will go to the trouble of making a test. In acute cases of gonorrhea such an application of heat prolonged for from thirty minutes to an hour will destroy every gonococcus reached by the heat.

J. A. FULTON, M.D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HOSPITAL EXPENDITURE—SIR E. CASSEL'S SECOND DONATION TO HOSPITALS—GUNSHOT WOUNDS OF CERVICAL VERTEBRÆ AND OF THE ABDOMEN. TREATED BY OPERATION.

LONDON, Dec. 23, 1915.

ANOTHER Xmas is at hand. Everyone is talking of the many modes of celebrating it, so even in a serious medical journal it may be excusable to refer to the joyous season. It is also natural to look back on some of the events of the closing year and the questions that have in its progress held our profession's attention. The expenditure of the 108 Lon-

don hospitals for the year amounted to £1,081,162—a slight increase over that of the preceding twelve months. The number of in-patients was, on the other hand, somewhat less, fewer beds being accordingly in constant use. The number of out-patients was also rather fewer. Among the in-patients of the year there were 5,478 naval or military cases, chiefly of wounded soldiers. This number was received on an understanding with the authorities during the latter months of 1914. A much greater number of such patients are being treated during the present year in the voluntary hospitals of London. The exceptional circumstances under which these hospitals had to carry on their work renders comparisons with previous years of little value. The rise in prices and the difficulties brought about by the departure for military and Red Cross duties of members of the medical, nursing, and administrative staffs greatly increased the cost of working, while at many hospitals the number of beds occupied was affected, either by some being added for the accommodation of the wounded or by others being kept vacant, in readiness for a sudden or unexpected demand. The necessity of preventing undue increase of cost is more obvious and urgent than ever and it is hoped will continue to receive the consideration of the King Edward Fund while it maintains the high standard of efficiency it has hitherto promoted.

Sir Edward Cassel's further munificent donation of £50,000 in the 4½ per cent War Loan Stock to hospitals and kindred charities is to be distributed on the same general lines as his previous donation of £50,000 made in 1911; that is, partly in direct gifts and partly through King Edward's Hospital Fund. The sum of £22,000 has accordingly been allotted by Sir Ernest to certain hospitals in varying amounts from £50 to £1,000. The £28,000 remaining beyond that has been entrusted by the donor to King Edward's Hospital Fund for the purpose of increasing by one-fifth the grants already made by the fund this year.

Wounds are the subject of numerous reports and discussions both at societies and elsewhere. At the Royal (Section of Laryngology) a soldier was shown who was wounded at Ypres in June by a bullet which entered over the right side of the nasal bridge, passing through the right maxillary antrum, the roof of the mouth, the tongue, and the left ramus of the lower jaw; then out at the left side of the larynx. The jaw which was fractured had been skilfully wired in place and had firmly united. The right antrum had been quite dark on transillumination for weeks, no doubt from blood clot, but had become clearer. A bullet wound in another soldier's neck must have injured the larynx, as a web now occupied nearly half the glottis, greatly impairing speech and breathing. An opinion was sought as to the treatment. The president, Dr. Bond, suggested laryngo-fissure in order to remove the web; Dr. McKenzie proposed diathermy. Another case of bullet wound in the neck was reported by Dr. McKenzie. It was inflicted on an officer in Gallipoli who became aware at the moment that he could only speak in a whisper. It healed in three weeks and the voice returned, so that he could converse comfortably, but shouting soon tired it. The laryngoscope showed the left vocal cord paralyzed. The bullet had entered the neck opposite the fourth cervical vertebra, emerging at the anterior border of the sternomastoid, midway between the upper edge of the thyroid cartilage and the hyoid

bone; so it must have been the left vagus which was severed, and yet there was no obvious damage to the carotids, the internal jugular, or the sympathetic. The pulse was normal, both in rate and rhythm. Another case of bullet wound was shown by Major Perry Goldsmith: it was of the left mastoid and left orbit with detachment of the retina. Dr. Watson Williams said he would not hesitate to open up the affected sinuses, particularly the sphenoids. Dr. Dundas Grant advised draining them. A bullet wound of the nose closed by plastic operation was shown by Dr. A. Wylie and a shrapnel wound of the nose and cheek by Dr. Pegler, who also showed a case of empyema of the right frontal sinus.

Abdominal wounds have always excited great attention, and C. Wallace who is consulting surgeon to the expeditionary force in France has contributed to the *Lancet* his views on the early treatment of those caused by gunshot. It is only recently that the usual systematic treatment has been by operation, and the rapid collection and transport of patients for this purpose has been well arranged; perhaps partly because of the belief that rest, morphine, and no mouth-feeding afforded the best chance of recovery. It was generally held that intestinal wounds healed by themselves, for as cases did recover in which a shot had passed through the abdomen it was assumed that the missile must have injured a hollow viscus. But recent operations have proved that this assumption is not justified. Blood and bile may set up the symptoms of peritonitis and many operations have revealed injuries such as perforations and divisions of the intestinal walls, a bullet being capable of doing as much damage as a fragment of shell. I meet no one who has had experience in the field who retains the old belief in the spontaneous cure of these wounds—except in the stomach, and only in that when the missile has taken an anteroposterior direction. Mr. Wallace suggests that in stomach wounds the non-protrusion of the mucous membrane is a factor in their spontaneous cure, since the pouting of the membrane would prevent a contiguous coil becoming adherent to the peritoneal surface while it can adhere to another part of that surface and be thereby shut off. If operation be done early some cases may present no lesion of intestine, yet a peritoneal cavity full of blood. Should the bleeding still be going on it will be arrested; in other cases, the bleeding point cannot be found or the hemorrhage may have ceased. In either case many lives are saved by early operation, and removal to a hospital where it can be at once performed should not be delayed. Less blood will be lost through the jolting of an ambulance than by leaving it to trickle away for hours. Symptoms of peritoneal involvement will be present in nearly every case by the time the hospital is reached, but they should not be waited for if the surgeon considers the wound has penetrated a dangerous area. A paramedian incision is the standard one for opening the abdomen and a long incision saves time, and consequently shock. Results will be reported later.

Private Woods of the Sixth Buffs was rendered dumb by the shock caused by the parapet of a trench falling upon him in France. He was transferred to the military hospital at Colchester, where he recovered his speech suddenly when one day his mother appeared unexpectedly at his bedside. At once he exclaimed "Mother!" and from that time continued to converse freely.

The soldier from whose brain a bullet was extracted in Belfast Hospital, after it had been buried there for three weeks is making a good recovery.

3. Insanity by Contagion. B. Henry Mason.
4. Notes of a Conference on the Medical and Social Aspects of Syphilis of the Nervous System. Latent Neurosyphilis and the Question of General Paresis, Sine Paresi. E. E. Southard and H. C. Solomon.
5. The Treatment of Headache. Justin Herold.

1. On Medical Testimony.—J. W. Courtney, in an address given before the graduating class of Harvard Medical School on November 19, 1915, gives some very practical advice to the medical man who is called to the witness stand. He says that any medical man who steps on the witness stand, armed with all the medical facts of his case, and who adheres closely to these facts in giving his testimony, has little to fear from cross-examination. His troubles begin the moment he allows himself to be drawn into the realm of speculation, and to venture opinions based on hypotheses. His testimony may embody the most scientific thought of the day, but unless it is couched in simple terms its sole effect upon the jury is generally a purely soporific one. Upon the stand the witness's manner should never be flippant, nor should it bear the stamp of spurious ease. His answers to counsel should be rigidly responsive; he should never volunteer a statement when no question is before him. Directly he steps on the stand he should have prominently in mind that he is the servant of the commonwealth. This does not mean that he is in any sense an advocate; quite the contrary. Therefore he should always refrain from argument with the counsel. He may find it difficult at times to give the desired answer "Yes" or "No," but it is always better to do so, because both the court and his own counsel will see to it that he has later an opportunity to amplify his statements to his entire satisfaction. He should sedulously avoid the answer "Not necessarily," which never serves other purpose than to get him deeper into the mire of cross-examination. He should not keep one eye on his own counsel and the other on the cross-examiner. His whole attention should be directed to the jury. He should not constantly appeal to the court when crowded by legitimate cross-questioning, and, above all things, he should never allow his voice to sink to an inaudible murmur, nor allow a display of temper to betray itself by shrill or petulant tones. He should shape his conduct so that through his efforts the ends of justice will really be accomplished.

2. Simplified Methods of Transfusion.—Edward H. Risley has recently tried out in the laboratory the various methods of transfusion. His experience leads him to make a few suggestions. It occurred to him to try, among other procedures, the collection of blood in a simple cylinder, uncoated with paraffin, but kept at body temperature by previous immersion in hot water (110°) and during transfusion wrapped in a hot towel wet in sterile water. This cylinder is a modification of the Kimpton-Brown tube which the writer has found easier to handle and less breakable. Using one part of a 2 per cent. citrate solution to ten parts of blood, he finds that transfusion is made extremely simple, safe, and sure by any of the various techniques one wishes to employ. This applies only to indirect transfusion. The author is almost equally divided between the use of the uncoated glass cylinder and the method by syringes. The purpose of the writer is to point out the value of ci-

trate solutions in transfusion and to show that almost any method can be made to succeed if this is used. He recommends that every physician who contemplates doing transfusion at all provide himself with the following apparatus: Two large (100 to 300-c.c.) glass cylinders, 500 c.c. of sterile sodium citrate solution in two bottles. (This can be sterilized by boiling repeatedly without deterioration.) Also a set of glass syringes (two 5 c.c. and one or two 20 c.c. and two 16-gauge cannula trochars). This outfit is sufficient to accomplish successfully any transfusion he is called upon to do.

3. Insanity by Contagion.—B. Henry Mason calls attention to a number of psychical epidemics of a hysterical nature recorded in history. He finds that insanity by contagion is met with at the present time, though it is more infrequent in its manifestations than it was a century or more ago. It is probable that contagion is in correlation with some underlying mental disorder. A mild contagion may be met with when a presumably normal individual adopts a delusive attitude, but in whom a diagnosis of communicable insanity would not be justified. One individual may impose his systematized paranoid delusional concepts upon another who is intellectually weaker than himself. A feeble-minded person may be so weak mentally that the intelligence is in every respect unproductive, but if the intellectual powers are but slightly inferior to the normal, then the individual is predisposed to communicated insanity. A person hereditarily predisposed to insanity may be the subject of contagion when intimately associated with an insane individual. The manifestations of mental disease may be simultaneous in two or more persons with an insane family taint.

4. Latent Neurosyphilis and the Question of General Paresis, Sine Paresi.—E. E. Southard and H. C. Solomon draw attention to a group of cases showing the laboratory signs characteristic of central nervous system syphilis—that is, positive Wassermann reaction in the serum and spinal fluid, pleocytosis, excess of globulin and of albumin in the spinal fluid, and the gold sol reaction of central nervous system syphilis, and which show no sign or symptom of neural syphilis. The writers believe these cases represent a form of chronic cerebrospinal syphilis probably paretic in type. They have the greatest theoretical and practical significance in the consideration of the life history of neural syphilis, on the concepts of allergie, in regard to results of treatment, and as to the evaluation of the laboratory tests. The authors believe that here is offered the last link to a chain between the symptoms of the primary stage of syphilis and its final termination of life as the result of cerebrospinal syphilis or general paresis.

6. The Normal Stomach. C. Winfield Perkins.
7. The Causes of Rickets. William Jacobsohn.
8. Syringing the Ear. Max Lubman.

1. Common Diseases of the Ear.—S. MacCuen Smith emphasized the importance of prophylactic measures, not only in the treatment of aural disease, but with a view of preventing its serious complications. During the catarrhal stage of acute suppurative otitis media the patient should receive divided doses of calomel, followed by a saline, and small frequently repeated doses of aconite. Rest in bed is of great value. Blood letting by means of an artificial leech in front of the tragus and douching with normal salt solution as hot as can

be borne every second or third hour are of assistance; or, in place of the douche, warm drops of a 10 to 15 per cent. carbolic acid in glycerine, or equal parts of tincture of opium and tincture of belladonna can be used. The same treatment is applicable to acute involvement of the mastoid process if seen by the physician in the early stage. But at this time the measure of the greatest prophylactic value in arresting an acute inflammation is free incision of the membrana tympani. Many cases of mastoiditis do not exhibit the classical symptoms, but there is one physical sign which is never wholly absent, unless the disease is confined to the tip, and that is drooping of the superior and posterior wall of the external auditory canal. In incising the membrana tympani the chief requisite is to carry the incision from the most bulging point downward to the lower border of the canal, and then continue it in an anterior or posterior direction until one-sixth part of a circle has been formed. This provides good drainage and insures the opening remaining patulous long enough to admit of proper after treatment. This simple treatment aborts the great majority of simple uncomplicated cases, but a goodly number of cases complicating influenza, the eruptive fevers, pneumonia, tuberculosis, and syphilis demand prompt surgical intervention.

2. Tuberculin Therapy.—Henry L. Shively says there is a general agreement among sanatorium physicians that patients who receive tuberculin treatment lose their bacilli more readily than patients who do not, that a greater proportion are discharged arrested, a larger number are restored to working efficiency, and that after a period of years their cure is better maintained than that of patients who have not had tuberculin. Besides these regular routine effects, which are gradually obtained over long periods of time, there are certain fortunate patients for whom tuberculin treatment is a real boost. The special field for tuberculin is that large group of patients with fairly good resistance, with little or no fever, stationary or slowly progressive, who are ineligible for or cannot go to a sanatorium, or who have failed to obtain a cure or an arrest while at a sanatorium. The time has come when the tuberculin treatment may be applied in private practice without danger and to advantage, or at least every tuberculosis clinic should have its tuberculin class. It is well for the beginner to select one preparation of tuberculin, preferably one representing all the substances contained in the bacilli; the best for all purposes is probably the bacillen emulsion. Hitherto the technique of the administration of tuberculin has been invested with unnecessary difficulties. A blood count, the determination of the opsonic index, or a complement fixation test, is of little practical value in treating the patient. Much time may be lost in beginning with or continuing too long with excessively minute doses. It is probable that doses of one-tenth million or even a millionth of a milligram are practically inert.

3. The Medical Treatment of Exceptional Children.—Tom A. Williams considers some of the physical causes which produce neurotic behavior in children, such as insufficient air and too tightly fitting clothing, incorrect food and drink, inadequate or improper exercise of the body, imperfect elimination and disordered glandular action. He says that since much of the food given to children has been deprived of its indigestible constituents, the husks of fiber and cellulose, the child eats too much meat, eggs and milk to get enough bulk. The best diet for the neurotic child, or any child, is a plentiful supply of such cereal foods as are prepared from whole grain, supplemented by an abundance of fruit, especially the banana. The psychological sources of disturbance to child life are mismanagement of attention

and mismanagement of emotion, sentiment, desires, inclinations, and intemperance and its contrary, over-repression. In connection with these author discusses affection, altruism, religiosity, fear, anxiety, scruples, obsessions and shame. He emphasizes the point that a child's mind needs work. Proper mental labor is essential for sound psychic health. The impression that growing organs should not be subjected to work is a gross error. The other extremes—over-sustained attention and over-intensity—are to be guarded against. Just as bones and muscle become strong by arduous exercise in childhood and early youth, so does the psyche become resistant to the "slings and arrows of outrageous fortune" by practice against them in childhood. It is a crime against the child not to give him practice in self-mastery against rebuffs, snubs, slights, and discouragement. In the treatment of these psychopathological conditions the most important thing even in children is to a realization of the situation. It is only when the patient can intelligently interpret the symptoms of a psychogenetic disorder that he is in a position to cause them to disappear. The patient does not get well from the analysis, but because of the psychic procedure adopted therefrom.

6. The Normal Stomach.—C. Winfield Perkins has made a röntgenological examination of fifty-eight normal stomachs from which he concludes that peristalsis does not seem to exert any influence on the tone of the stomach; that there are no determined fixed points of any type of stomach in the abdominal cavity except the cardiac portion; that a stomach may be of any of the types and yet be normal from an x-ray standpoint; that the average normal stomach is orthotonic. The usual position of the orthotonic stomach is as follows: Greater curvature (lowest point) one to two inches above the interspinous line, either median or to the left; lesser curvature (lowest point) three to four inches above the same line, median or one to two inches to the right. The pylorus is placed two or three inches above the line, in the median position or one and a half inches to the right. The axis of the stomach is vertical and parallel to the median line. The length is eight to ten inches and the width three to three and a half inches. The tendency of the male stomach is always toward hypertonicity, while that of the female is toward hypotonicity. The stomach is not, as a rule, as high in the abdominal cavity as many textbooks of anatomy teach. There is no structure in the human body that has such variations in form, tone, and position. A chart of the relative positions of the stomach should be of service to the clinical diagnostician in locating pathological lesions of the organ if x-ray methods are not at hand.

1. The Treatment of Respiratory Diseases in Infancy and Childhood.—John Lovett Morse discusses more particularly the value of "fresh air" in the treatment of respiratory diseases in infancy and childhood. He says that it is evident that as fresh air is the opposite of bad or close air, the essential characteristics of fresh air are not freedom from carbon-dioxide or a hypothetical organic poison, but coolness, dryness, and motion of the air. Therefore, fresh air may be defined as air which is cool, dry, and in motion. Fresh air need not necessarily be pure air, if by pure air is meant air which does not contain bacteria or dust. The writer discusses the action of cold air on the respiratory mucous membrane and that which it exerts on the system as a whole, and concludes that fresh air is of advantage in the treatment of all diseases of the respiratory tract. It is also of advantage to have the air pure—that is, free from bacteria, dust, and smoke. Cold air is of advantage in some conditions, but harmful in others. In children in the early stage of acute nasopharyngitis, in acute laryngitis, and in the early stages of acute bronchitis, whether or not associated with dyspnea and cyanosis, cold air has a strong irritant action on the inflamed mucous membrane. During the later stages of acute bronchitis, in cases in which bronchopneumonia has developed, the most acute stage of the causative bronchitis having passed, and in lobar pneumonia where the bronchial mucous membrane is not involved, there is no contraindication to the use of cold air. There is no question that children with lobar pneumonia are more comfortable in cold air than in warm, but they must be dressed for it. It is sufficient to expose the face. The body must be warmly covered and protected. It is not possible to treat all diseases of the respiratory tract in the same way.

2. Child Welfare and Tuberculosis.—Sherman C. Kingsley publishes the results of a study made by a committee appointed by the Mississippi Valley Tuberculosis Conference, having for its object the arrangement of a program of activities for the promotion and safeguarding of the physical welfare of children and the prevention of tuberculosis among them in the conference territory. The report includes a comparative study of the physical condition of children in rural and urban communities which shows that rural children are less healthy and are handicapped by more physical defects than city children. The better showing made by the cities in this respect are attributable to the work of health departments and child-welfare agencies. If tuberculosis is to be prevented a more complete and effectual work must be done with the children. Our program must begin with them when they are babies. Infant-welfare work should be made universal in this country as it is in New Zealand, where through such efforts the death rate of babies for the whole country has been reduced to fifty-one out of 1,000. The next great goal is to see to it that in the school period the needs of the school-children are recognized and understood. We should fight the fight in the earlier and more promising years of childhood and not wait until the same defects and conditions which produced failure in school become the causes of failure for life.

4. Urochromogen Reaction.—Alexander M. Burgess

presents a study of the relation of the occurrence of urochromogen reaction in the urine of tuberculous and nontuberculous patients to the stage of the disease present, and to the ultimate prognosis. The number of tests carried out in studying 171 patients suffering from advanced tuberculosis was 469; in studying 650 cases of nontuberculous disease, 1,030. From the results obtained the writer concludes that the urochromogen reaction is of no value in determining the prognosis in diphtheria, scarlet fever, and measles; that in advanced tuberculosis a positive reaction indicates a severe and actively progressing lesion which will probably lead to death in six months, and that a negative reaction in advanced tuberculosis is of no value.

8. **Intestinal Anastomosis.**—Golder L. McWhorter describes his modification of the technique of the right angle and his new method of notch enterorrhaphy. In the technique of the right angle he cuts the bowel at an angle of 45 degrees, leaving the oblique mesenteric sides. The mesenteric portions are approximated first by a mattress suture, which when tied on the inside occludes the uncovered area of the bowel and invaginates the edges. With a needle on each end of this suture they are continued around so that this mesenteric half is first sutured accurately with a hemostat button-hole stitch. These are then continued as Connell sutures, ending at that end of the bowel opposite the mesentery. A Dupuytren's stitch is now taken outside the first stitch to approximate a wide area of serosa. A few stitches join the mesenteries. The right-angle union has advantages over the usual end-to-end in that it not only has a richer blood supply but the angle of the blood vessels toward the union lessens the danger of the second row of sutures causing gangrene of the inverted margin of the bowel. In the new method of notched enterorrhaphy, after deciding upon the area to be resected and preparing the field, the mesenteric vessels supplying the bowel to be resected are ligated. Double clamps are put on the ends of that portion to be resected. The bowel is cut between the clamps with a cautery, leaving them temporarily on the ends to be united. The ends of the bowel that are to be united are overlapped for union as far as may be desired, restoring the direction of peristalsis; two inches is usually satisfactory. A Dupuytren's stitch taken along the sides near the mesentery approximates them. The clamps temporarily holding the ends of the bowel closed are cut away and the sides of the intestine which approximate each other are nearly cut away, beginning at the end of the lumen and leaving a small edge of the side near the mesentery for the approximation of serosa by an inner stitch through all the coats of the bowel. A similar width of the bowel is left on the convex side for approximation and invagination by sutures. These notched sections of the bowel should have rounded corners in order that they may be accurately approximated. A hemostatic button-hole stitch started on the inner side near the mesentery through all the coats of the bowel and continued around the other side as a Connell suture invaginates the edges. The Dupuytren's stitch previously started is now continued around the first suture line, approximating a safe margin of serosa. The notched anastomosis has the advantage that a large opening can be secured as well as one that functions satisfactorily.

10. **"Autolysin" in Mouse Tumors.**—Francis Carter Wood, after making tests in twenty-one animals bearing spontaneous tumors, concludes that "autolysin," either in small or very large doses, does not affect malignant tumors in mice.

11. **The Extent and Significance of Gonorrhea in a Reformatory for Women.**—Elizabeth A. Sullivan and Edith R. Spaulding present an exhaustive study of the

problem of gonorrhea in the Reformatory for Women at Framingham, Mass. They find that the facts that stand out most prominently are: (1) That among delinquent women in general 75 per cent. at least have a gonorrheal infection. This is a very conservative estimate of the number who at some time have had the disease. Among the prostitute class, however, the proportion of gonorrheics increases to over 98 per cent. (2) Sixty-seven per cent. of the positive cases present symptoms of pelvic inflammation while 40 per cent. become surgical cases. (3) The birthrate appears to be diminished over one-half on account of the disease, and 35 per cent. of the positive cases present "one-child" sterilities. (4) Gonorrheal ophthalmia and endocarditis are among the serious complications. (5) The majority of cases have apparently run an uninterrupted course sometimes for a period of twenty-five years without treatment, and during that time have been a prolific source of infection in the community. Methods that suggest themselves for dealing with this problem are segregation, early diagnosis, and intensive treatment of all persons who pass through the courts and are detained in public institutions on any charge, and the provision throughout the country of hospitals for the treatment of such persons, if necessary, free of charge. Treatment may be given in special wards of general hospitals because of the stigma attached to hospitals for the exclusive treatment of venereal diseases.

12. **The Incidence of Syphilis Among Juvenile Delinquents.**—Thomas H. Haines has made a study of 147 boys in the Boys' Industrial Home and 218 girls in the Girls' Industrial Home in Ohio with reference to the relation of syphilis to mental deficiency. He concludes that from the evidence at hand it seems impossible to charge congenital syphilis as a cause of mental impairment in these cases of delinquents. No larger percentage of those yielding positive Wassermann reactions are defective in intelligence than in the general population of these reform schools. There is complete absence of evidence of the signs of congenital syphilis in thirty positive cases examined. Cases of positive Wassermanns, with sister or father yielding a negative Wassermann, point to individual infection. The court charges against the girls in a majority of the cases, and the extent of sexual immorality, allow of abundant opportunity for individual infection. The absence of evidence of syphilis in personal history and in the medical certificates can be given no weight either for or against individual infection. The absence or exaggeration of deep reflexes without difference in the two sides of the body, and without disturbance of the light reflex of the pupil, indicates that if these signs are due to syphilis of the nervous system they are early signs, and so far tend toward evidence for individual infection.

15. **Pott's Disease Treated by Operation.**—W. E. Wolcott makes a preliminary report on 682 cases of Pott's disease operated upon by sixteen surgeons located throughout the country. In the series there was a mortality of 5 per cent., not directly attributable to operation. Of 642 operative cases 83 per cent. were benefited by the operation. From an analysis of this series the writer concludes that there is no doubt that these operations, in a large percentage of cases, abbreviate the treatment of tuberculosis of the spine by definitely hastening the curative ankylosis. By hastening ankylosis the likelihood of an increase in the deformity is proportionately decreased. These operations are undoubtedly best adapted to the treatment of Pott's disease that involves the cervicodorsal or dorsolumbar regions. Ankylosis of several vertebræ in this region is not associated with any serious amount of limitation of motion if unattended by marked deformity. On the

other hand, as approximately 75 per cent. of Pott's disease involving the cervical and lumbar regions develop but a slight degree of deformity when treated by external appliances, and since the development of ankylosis of several vertebrae by operation in either of these regions would be associated with marked restriction of motion in the majority of cases, it would seem best not to be too hasty in advising operation in either of these regions. It seems to be the general opinion of the majority of the contributors that the operation should be considered only as one phase of the treatment for Pott's disease and that supportive treatment should be continued until all signs of active disease have disappeared.

4. Another Human Coccidium from the Mediterranean War Area. C. M. Wenyon.

1. **Wounds in War.**—Anthony Bowlby chose this subject for the Bradshaw lecture which he delivered before the Royal College of Surgeons of England, on December 20, 1915. Having served in two campaigns, the lecturer contrasted the conditions under which war was conducted in South Africa with those that have prevailed in Flanders. The Boer campaign was conducted mostly in dry sunny weather, in wide wastes never brought under cultivation, and far from human habitations. France and Belgium are lands of copious rainfall, with frequent cloudy days, civilized and cultivated for nearly two thousand years; their population is dense, their rich loamy soil allows of luxuriant crops, is freely manured, and supports cattle and poultry in abundance. In consequence all septic microorganisms, including one of the worst, practically unknown in civil life, flourish even deep down from the surface of the soil. Wounds are therefore infected from the first, and are at the same time very severe owing to the character of the missiles employed. Mud, dust, and pieces of stone from the soil or the trenches are blown into the wound; the expansion of gas is alone sufficient to kill, as in one case in which numerous minute hemorrhages were detected in the brain; a bullet in its passage through the tissues exerts great force from within outward, and imparts its momentum to the fragments of bone which it shatters. Muscles and solid organs are widely damaged, as is shown by microscopical examinations, illustrations of which serve to illustrate the lecture. This far extended microscopic damage favors septic infection. The lecturer spoke of the beneficent results of subcutaneous or intravenous injections of normal saline solution, of enemas of hot water and brandy, and of pituitary extract in those suffering from shock and collapse following wounds, and called particular attention to the gas forming anerobes, which were found in almost every wound in this war; they attacked the tissues more rapidly and violently than other organisms, and multiplied freely in the dying substance in the midst of the muscles and harder structures damaged by the expanding force of the projectile. He believes that while the severe wounds caused by modern projectiles can hardly be sterilized at a single dressing, antiseptics are useful and necessary for their proper treatment. The period during which the saline hypertonic treatment is useful is strictly limited to the separation of sloughing and unhealthy tissues, and once a granulating surface is obtained throughout it had better be abandoned. He also expresses a very decided opinion that the hypo-

chlorous acid treatment is an important advance, more especially when used in recent wounds before suppuration has occurred, and states that it has to a great extent displaced all other forms of treatment in many of the casualty clearing stations. It should, however, be only used in solution. Efficient drainage in all wounds of war cannot be too strongly emphasized; the stimulus of Sir Almroth Wright's work in this field has been of inestimable value in promoting sound practice along these lines.

2. **Bactericidal Effect of Ethylhydrocupreine.**—A. C. Inman has been investigating the bactericidal power of ethylhydrocupreine (optochin) on a fecal streptococcus obtained from wounds, and finds that it has very limited powers of penetration. This fact would seriously limit its efficacy in the treatment of bacterial infections, for it would be unable to diffuse into and exert its influence in abscess cavities, infiltrated tissues, and other dead spaces. It would appear that it might find a useful sphere of application in cases of streptococcal bacteriemia; but it has not yet been put to this test.

3. **Functional Nerve Disease and the Shock of Battle.**—David Forsyth presents a study of the so-called traumatic neuroses, cases of which have become unprecedentedly numerous since the outbreak of the war. The clinical picture in these cases is best described as that of "nervous exhaustion." It seems that the intensity of the shock is measured in terms not of the trauma, but of the sensitiveness of the individual, a psychopathic tendency having been noted by the writer in all cases coming under his notice. Some cases recover with rest and quiet in the course of a few months; in others the treatment must follow psychoanalytic methods. With an increasing experience the writer entertains a strong doubt as to the judiciousness of sending any case of nerve shock, with few exceptions, back to the firing line. If this source of anxiety could be removed the patient's chance of making a speedy recovery would be increased.

4. **Another Human Coccidium from the Mediterranean War Area.**—C. M. Wenyon reports that he has encountered a coccidium which produces within the oöcyst four sporocysts, each of which has two sporozoites and a residual body, so that it must be placed in the genus *Eimeria* (Coccidium). This coccidium resembles most nearly the parasite of the mouse, though it is impossible to state definitely if it is actually this species or one quite distinct.

6. The Character and Treatment of Frostbite. H. E. Munroe.

2. **Iodine and Sodium Hypochlorite as Wound Disinfectants.**—Harry Schütze has carried out a number of laboratory tests with reference to the effect of phenol, iodine, and Dakin's hypochlorite solution as wound disinfectants. These experiments show the failure of 5 per cent. phenol to sterile malignant edema spores and the difficulty with which iodine does so, whether serum be present or not. Dakin's solution even in one-half the strength in which it is usually employed is, on the other hand, in the absence of serum, most effective. Even small quantities of serum, however, can interfere with its action; this would lead one to expect no direct lethal effect of the solution on similar resistant spores embedded in the tissues of a wound unless by irrigation the serous fluid surrounding these spores could be re-

placed to well above 95 per cent. by the hypochlorite solution.

3. Quinine Hydrochloride Solution as a Dressing for Infected Wounds.—Kenneth Taylor finds that the clinical experience with quinine hydrochloride has been consistent with the laboratory work previously reported. It has been active in ridding heavily contaminated wounds of the gas bacillus, acting as an antiferment, inhibiting the activity of the putrefactive organisms, and reducing the offensive odor associated with them. The solution does not appear to be precipitated by the serum or discharge from wounds in the case of the 1 per cent. solution. The one-tenth per cent. solution has occasionally shown precipitation without the addition of one-tenth per cent. hydrochloric acid or 1 per cent. of alcohol. The addition of neither of these drugs has appreciably increased the bactericidal activity of the quinine solution *in vitro*, but appears to prevent precipitation of the alkaloid caused by the strongly alkaline discharge present in some profusely suppurating wounds.

4. Notes on Traumatic and Venous Aneurysm.—F. L. A. Greaves relates the history and symptoms of four cases, and compares some of the points with the description in Keen's Surgery. The textbook states that the time of appearance is from four hours up to many weeks after injury; in three of these cases it was observed in from twenty-four hours to three days. Ecchymosis of the skin is stated to be seen when the vessels are superficial; this was only noticed in one case and was not a marked symptom. The murmur is stated to be heard by the patient if the aneurysm is in the subclavian or carotid regions. Neither of the subclavian cases here reported could hear his own murmur. Superficial veins above and below the aneurysm are said to be dilated, tortuous, or pulsating with systole. Very slight dilatation of a vein was seen on one subclavian case; none whatever in the others. Tortuousness and dilatation with systole were not seen in any case.

November 22, 1915.

Arthritis Deformans in the Light of New Research.

—Axhausen objects that a recent general review of this subject did not do justice to several important papers of recent date, including one of his own. The author believes he has established the fact that a primary total or partial necrosis of the joint cartilages is one component of this affection. With this is conjoined a proliferation of cartilage and subchondral tissues. The relationship between these processes is not clear, so that the author resorted to experiment. First, joint cartilage was destroyed in spots by electrolysis. This destruction thereupon called forth the proliferative phenomena. The author was enabled to make similar experiments in mankind, and, without going into particulars, he claims that a complete parallelism exists between the natural and experimental. The origin and nature of the necrotic process in the spontaneous disease forms the crux in the case, and much histological study has been carried out to solve these problems. The author does little in this direction, his article becoming almost entirely controversial in defending his assumptions against those of his colleagues.

Primary Generalized Spindle-Cell Sarcoma of the Lymphnodes.—Von Baumgarten shows in a reported case that genuine sarcoma may replace lymphosarcoma in this incidence. From a patient with alleged lymphatic leucemia two enlarged nodes were excised for microscopic study and found to be the seat of spindle-cell sarcoma. The patient, an elderly man, had first noted the presence of enlarged axillary glands to the

right. When examined adenopathy was found in various localities, others being exempt. Some of the enlarged nodes were significant of serious disturbance (anterior mediastinal) while others seemed merely casual. Certain lesions in the skin doubtless represented a lymph-stasis. The liver and spleen were both enlarged. Blood count showed red cells and lymphocytes reduced in quantity. Under arsenic there was considerable improvement, but hemoglobin fell. At this point two nodes—one a swollen gland and the other a cutaneous nodule—were excised with diagnosis as above stated. The patient after his slight improvement went rapidly from bad to worse with various intrathoracic symptoms. The left leg and right arm were edematous. The lymphnodes of the major flexures were all considerably enlarged, forming in some cases paquets. Nodules in the skin suggested metastases. Ascites had developed. There was no benefit from x-rays. The author gives most elaborate autopsy finds, as befits the importance of the case, which appears to be almost or quite unique. The diagnosis originally made of lymphadenosis aleucemia had to be renounced. Aside from the evidence of spindle-cell sarcoma the blood picture did not agree with the first diagnosis. Pathological lymphocytes were absent throughout, while normal lymphocytes were down to $6\frac{1}{2}$ per cent. Local spindle-cell sarcoma of lymphnodes is not rare, but the type is large cell. The author's case was a sarcomatosis of the entire glands with the small type of cell. It would be easy to claim that this sarcomatosis was all metastatic, but the author searched the entire cadaver in vain for a primary focus. Secondary sarcomatosis was excluded by the virtual absence of metastases in localities other than in the lymphnodes and by the fact that metastases in such cases are regional. The nodules in the skin of the thorax were doubtless due to backward lymphatic propagation, from the enlarged axillary nodules. The thoracic cavity was the seat of enlarged nodes, both mediastinal and tracheobronchial, with recent pleurisy of one side and adhesions in the opposite cavity, with a high degree of arteriosclerosis of the aorta.

The Oligodynamic Action of Copper.—Spiro recalls the discovery of Naegeli that metallic copper is able to kill algæ, *i.e.* when the latter are placed in water contained in a copper vessel they cannot survive. The amount of copper actually in solution is minimal. Naegeli calls this action an oligodynamic one, and states that it is possessed by a number of metals, etc., the salts of which are toxic. Israel then sought to determine whether this form of activity was or was not specific. The author is especially interested in the problem of direct or indirect action. Does the trace of copper combine with something in the cell, or is the action a catalytic one? The addition of certain substances placed in the water causes the copper of the vessel to go into solution (H_2O_2); in other words, solution of copper is due to an oxidative process. In the case of algæ, bacteria, etc., the oxygen contained in these organisms must be responsible for the solution and binding of the copper in the dish, adsorption being a factor in the process. In what manner could this slight increment of copper poison the organisms in question. We have to think of the possible formation of cyanogen compounds and of ferment catalysators. The oligodynamic action has at first sight nothing in common with the specific (caustic) action of copper on the tissues. But the latter consists in the union of a copper salt with the tissue albumin, and there seems to be no evidence to show that the oligodynamic action has a different mechanism.

Therapeutic Action of Colloidal Silver.—Bersch thinks this remedy for sepsis much undervalued in textbooks. Recently, in a base hospital, he tested it on a subject who was thought to have pneumonia, but was really suffering from a typical sepsis. The symptoms were headache, thirst, and exhaustion; fever with typical septic curve—violent chills, followed by fever of 40° C., sinking at times as low as 35.8°, with profuse perspiration—lasting three weeks. The chill, rise, fall, and sweating occurred daily, beginning in the afternoon. The subject showed evidence of septic endocarditis, pulse 160, feeble. The principal treatment was digitalis for the heart, but the response of the latter was becoming less marked. Under intravenous injection of colloidal silver the symptoms changed for the better and the patient made a slow but complete recovery.

Cure of a Vulval Cancer by Zeller's Method.—Reusch relates the following case: A woman of sixty-two was attacked by profuse hemorrhage from the vagina. Her health had been failing, but she had had no local symptoms beyond hemorrhage. Only when the labia majora were separated did an ulcerated carcinoma come into view. This had originated on the inner aspect of the right labium majus and then involved the labium minus and clitoris. There were no enlarged inguinal glands. The patient refused both the knife and radiotherapy. Nothing was left but to employ the caustic-paste method of Zeller first recommended in 1912, which has never received the attention it merits. The formula is as follows: R. Acid. arsen., 2.0; hydrarg. sulphur. rubr., 6.0; carbo. animal, 2.0. Misc. This powder is made into a paste with water. The mixture of silicates of potash and soda was given inwardly. Both these remedies were devised for Czerny's Cancer Institute. The paste caused a violent phlegmonous inflammation *in situ* extending down the thigh and up the abdomen. For the first time the inguinal lymphnodes became swollen. The patient had to be kept under morphine. In about two weeks a great slough came away comprising the entire cancer. A course of radiography now followed and the cancer area healed over completely. Nine months have now passed without recurrence, although the enlarged lymphnodes have never undergone resolution.

Late Tetanus After Prophylactic Injections of Antitoxin.—Teutschlander relates a case of a fatality due to tetanus bacilli occurring 145 days after a shell wound which had furnished the port of entry for the germs. The prophylactic injection of antitoxin appeared to have been responsible for this long period of latency. The sudden development and rapid, fatal type of disease showed that there had been a general awakening of virulent germs. The actual determining cause of the disease was a resection of the ribs for empyema in the immediate neighborhood of the scar of the shell wound. Late tetanus in connection with scars is no new subject, but in the old cases of this incidence there was no special reason for suspecting tetanus infection of wounds, and tetanus antitoxin had not then come into use. Moreover, the alleged period of latency in some of these cases amounted to several years, and it would have been more reasonable to accuse some overlooked or cryptogenetic source of infection. In a few recently published cases in man and horse the conditions were parallel with those in the author's case, *i.e.* antitoxin was injected after wound or operation and tetanus developed in from two to five months in the scar. This subject of late tetanus deferred by prophylactic injections of antitoxin will no doubt constitute a problem to be reckoned with in the future. The author calls attention to some points

of interest involved: Wherever there is a notable proliferation of granulation tissue in a recent wound tetanus germs may be walled in and eventually be retained in the scar without giving rise to symptoms. These shut-in germs may remain alive and able to reproduce themselves and secrete toxin. An injury to the scar may mobilize the bacilli or the toxin, and cause fulminating tetanus, and this may even occur after a number of years. Antitoxin given as a prophylactic can neutralize any toxin that reaches the blood, but is powerless against the shut-in germs themselves. The sole resources in these cases are surgical—prevention of healing-in of foreign matter and extirpation of scar-tissue.

A Quarter Century of Antitoxin Therapy.—Kossel shows by means of a simple chart the relationship between diphtheria deaths and antitoxin treatment in German cities of over 15,000 population for the twenty-nine years preceding 1915. The figures begin in 1886, antitoxin therapy having been introduced in 1894-1895. In preantitoxin days there were relatively high mortalities in 1886 and 1893, while in 1891 the death rate was relatively low. Antitoxin was introduced in 1894, when the mortality was reactionary, corresponding to that of 1891. By 1895 there had been an unprecedented drop, instead of an equilibrium or rise. The fall continued with less pronounced breaks until 1900. Since that time it has not changed materially, and even the "severe" epidemic of 1911 makes but the slightest ripple in the almost constant curve. No one can dispute the truth of the chart, and from enemies and skeptics as to serotherapy the only argument can be that diphtheria has yielded to other factors, which would be an unexampled begging of the question. Serotherapy, however, really began with Koch's tuberculin treatment, which enables us to speak of its quarter century anniversary, antitoxin in the strict sense being but one expression of it, although all serotherapy has a common province in immunization activities.

Glucose as Prophylactic of Shock.—A. C. Burnham advocates the administration of glucose solution as a routine measure after every operation in which there is reason to fear more than the ordinary amount of postanesthetic shock; it should be given in every case in which post-operative oral feeding may be difficult or insufficient for a considerable period after operation; it should be given as an emergency measure either before or after operation for the relief of an existing or threatened acidosis. Kausch has recommended 7 per cent. solutions intravenously and 4 to 5 per cent. solutions by hypodermoclysis. Solutions should be freshly prepared and sterilized, as they become more easily contaminated than does the ordinary saline. Strictly speaking, contamination is as easy in one as in the other, but owing to the fact that glucose is an excellent culture medium, accidental contamination is of more consequence than in the case of common salt solution. Following the use of glucose by hypodermoclysis there is no more pain or discomfort than after the injection of physiological salt solutions. As much as two or three liters, representing from 90 to 210 grams of glucose, may be given during twenty-four hours, the amount depending on the character of the case and the urgency of the symptoms. In addition to the hypodermic administration, glucose may be given by proctoclysis during anesthesia and for a period of several days after operation. It is given in 5 per cent. solution, dissolved in ordinary tap water, 12 to 16 ounces being introduced during the operation, and its administration continued by the Murphy drip method, after the patient has returned to the ward.—*American Journal of the Medical Sciences.*

Book Reviews.

MANUAL OF EMBRYOLOGY. By A. MELVILLE PATERSON, M.D., F.R.C.S., Professor of Anatomy in the University of Liverpool. Member of the Institute of American Anatomists. Past President of the Anatomical Society of Great Britain and Ireland, etc., pp. 391. Price, \$2.75. London: Henry Frowde, Oxford University Press, Hodder and Stoughton, 1915.

THIS volume is worthy of note because it has condensed the entire subject of human and comparative embryology into less than 100,000 words of actual text; because it has three-fourths as many illustrations as pages, giving it the status of an atlas; and because every significant word or term, besides being printed in the text in full face type is duly indexed. The index contains about 1,200 titles and is therefore neither scanty nor redundant. Each of the over 300 illustrations is made quite independent of the text by topical designations and a full legend. Everything seems to have been done for the student without minimizing the innate difficulties of the subject.

A MANUAL OF SURGERY FOR STUDENTS AND PHYSICIANS. By FRANCIS T. STEWART, M.D., Professor of Clinical Surgery, Jefferson Medical College; Surgeon to the Germantown Hospital; Out-Patient Surgeon to the Pennsylvania Hospital. Fourth edition. Octavo of 774 pages with 580 illustrations. Price, cloth, \$4.00 net. Philadelphia: P. Blakiston's Son & Company, 1915.

IN the preface to the first edition the author stated that his main aim had been to be brief and practical; and that the chief desire had been "to set down concisely and completely those facts which the student must know and to make such suggestions in diagnosis and treatment as will best aid the physician in his daily practice." Stewart's experience as a teacher stood him in such good stead that a fourth edition of the work is already demanded. In this edition he has revised certain sections of the work, expanded others, and added a number of sections in order to cover those branches of surgery in which there have been marked advances in operative technique or in diagnostic methods, or where surgery has invaded new fields, as in the treatment of hemorrhagic conditions by transfusion.

In general, Stewart has covered the subject concisely and well; though it was rather too much to hope to cover it "completely" in a relatively small work of this character designed for undergraduates and as a "guide" for practitioners. For instance, in the section on transfusion several methods are detailed, including that by arteriovenous anastomosis and the use of the Kimpton tube. Strangely enough, while the citrate method is mentioned, that of Lindeman, the most widely used of any up to the elaboration of the Lewisohn-Weil technique, receives no notice. Again, we occasionally see inaccuracy of statement, or a statement which should have at least been qualified in some way. A case in point occurs on page 416, where we find the following: "The parathyroid glands are four in number. They are brownish red, oval bodies, . . . one near the pole of each lobe." While this may be true in a certain proportion of the cases, it has long been known that the parathyroids are very variable, not only in position but also in number. Typographical errors are not at all infrequent. For example, Graves' disease is regularly called Grave's disease.

While other errors of omission or commission might easily be cited, we do not feel that it is necessary to do so; for the book as a whole is extremely well written and seems unusually well fitted for the class of readers for which it was intended. The author has fulfilled his promise to be concise, the most practical points in diagnosis and treatment are well brought out, and his statements are usually accurate.

A MANUAL OF THE PRACTICE OF MEDICINE. Prepared Especially for Students. By A. A. STEVENS, A.M., M.D., Professor of Therapeutics and Clinical Medicine in the Woman's Medical College of Pennsylvania; Lecturer on Medicine in the University of Pennsylvania; Physician to the Philadelphia General Hospital, to the Episcopal Hospital, and to St. Agnes' Hospital; Fellow of the College of Physicians of Philadelphia, etc. Tenth edition, illustrated. Price, \$2.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

THIS new edition has been brought up to date by the insertion of information on Vincent's angina, divert-

icula of the esophagus, acholuric jaundice, embolism and thrombosis of the mesenteric vessels, alcaptonuria, albumosuria, tests of the functional capacity of the kidneys, polycystic disease and malignant disease of the kidney, chronic enlargements of the spleen, hypopituitarism, infantilism, glandular fever, Rocky Mountain spotted fever, Weil's disease, kala-azar, congenital amyotonia, and myasthenia gravis. A few other articles have been slightly modified, otherwise the book remains as before.

A MANUAL FOR MIDWIVES. By C. NEPEAN LONGRIDGE, M.D. (Vict.), F.R.C.S. (Eng.), M.R.C.P. (Lond.). Examiner to the Central Midwives Board, Late Resident Medical Officer at Queen Charlotte's Hospital, Lecturer on Midwifery for London County Council; and JOHN BRIGHT BANISTER, M.A., M.D., B.C. (Camb.), M.R.C.P. (Lond.), F.R.C.S. (Edin.). Physician to Out-Patients Queen Charlotte's Hospital; Surgeon to Out-Patients; Chelsea Hospital for Women; Assistant Gynecologist Prince of Wales' Hospital, Tottenham; Examiner to the Central Midwives' Board; Lecturer in Midwifery Maternity Nursing Association. Second edition. With fifty-one illustrations. Price, 85c. net. London: J. and A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1915.

THE authors of this little manual are to be congratulated on having performed most creditably a difficult task. They have produced a book scientifically correct, couched in the simplest language, and written so clearly and concisely that it may be said to set a standard for books for nurses. With good paper, large print and original illustrations, it is difficult to see how the publishers are able to offer the volume at so reasonable a price. It is far superior, both in appearance and contents, to many volumes of the kind that cost three or four times as much.

NURSING IN DISEASES OF THE EYE, EAR, NOSE, AND THROAT. By THE COMMITTEE ON NURSES OF THE MANHATTAN EYE, EAR, AND THROAT HOSPITAL. Second edition, thoroughly revised. Price, \$1.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

THE first edition of this work was reviewed in these columns on its appearance a few years ago. It is, therefore, only necessary now to draw attention to the new edition, and to say that the present revision contains a new chapter on "preparation of surgical dressings," and sections on "mental disturbances after operations on the eye" and "functional test of the static labyrinth." The general get up of the book, and its size and price are alike attractive.

COLLECTED PAPERS OF THE MAYO CLINIC, ROCHESTER, MINN. Edited by Mrs. M. H. MELLISH. Volume VI, 1914. Octavo of 814 pages with 349 illustrations. Price, cloth, \$5.50 net; half-morocco, \$7.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

THERE are no less than 75 articles in this volume, grouped under six general headings as follows: nineteen articles in the first section, which is devoted to the Alimentary Canal; nine in the section on Urogenital Organs; five in that on the Ductless Glands; sixteen in that on Head, Trunk and Extremities; eight on Technique; and eighteen under the title General Papers. In the foreword of this book we find the suggestion that the amount of material emanating from the Mayo Clinic in the course of a year is getting to be so great that in order for it to appear in a single volume of reasonable size condensation is necessary when possible. To this end, we are told, it has seemed expedient "to abstract for the present volume some of the articles, the material for which has been partially covered in this or in previous volumes." The hope is expressed "that this method will serve to give a clearer conception of the relationship of researches on one subject by the same investigator as well as to reduce the size of the volume."

Since the articles herein contained are the work of many (81) authors and have all been published elsewhere, and since such a large field is covered, it would be manifestly unfair to single out special articles for comment. Suffice it to say that the book is of value not only to the surgeon but also to the progressive general practitioner who realizes that he must keep in touch with the advances in the field of surgery and allied sciences if he would be in a position to safeguard the interests of his patients.

Society Reports.

JOINT MEETING OF THE NEW ENGLAND PEDIATRIC SOCIETY, THE PHILADELPHIA PEDIATRIC SOCIETY, AND THE SECTION ON PEDIATRICS OF THE NEW YORK ACADEMY OF MEDICINE.

Special Meeting, Held in Philadelphia November 9, 1915.

Dr. WILLIAM N. BRADLEY OF PHILADELPHIA IN THE CHAIR.

THE members of the Philadelphia Pediatric Society entertained the guests during the day with clinics, short talks, and demonstrations in various hospitals and research laboratories of the city. Among the institutions visited were the following: Henry Phipps Institute of the University of Pennsylvania for the Study, Prevention and Treatment of Tuberculosis; Jefferson Hospital, where Dr. E. E. Graham gave a clinic; the Health Center of the Child's Federation, where Dr. S. McC. Hamill explained the intensive work which was being conducted for the prevention of diseases in a congested foreign quarter of the city, the first unit of the new group of buildings of the Children's Hospital, and the Children's Building of the Woman's Hospital, where luncheon was served to the visiting physicians. The greater part of the afternoon was spent in the various departments of the University of Pennsylvania. Here three talks were given in the Department of Research Medicine of the Laboratories of Pathology, Physiology, and Pharmacology. These were as follows:

Acidosis in Children.—Dr. ALONZO E. TAYLOR of Philadelphia gave this talk in which he described the work they had been doing in their endeavor to determine the actual relation of intermittent vomiting to acidosis. They had studied the elimination in a child whose diet was known before, during, and after the attacks of vomiting. The urine was also examined forty-eight hours before the onset of the attack. The quantitative determination of the acid elimination, ascertained by estimating the quantity of the different ketones, showed that for two days previous to the attack there was no acidosis; acidosis did not show itself until three days after the onset of the vomiting. The ketonuria continued until the child was again taking a normal diet when it dropped to normal. These findings seemed to indicate that the ketonuria was the direct result of the starvation and had no direct connection with the intermittent vomiting. The conclusion seemed to be warranted that there were two types of acidosis; one connected with intermittent vomiting, and one dependent on the withdrawal of food and having nothing to do with the intermittent vomiting.

Metabolism Studies Before and After Splenectomy in Congenital Hemolytic Icterus.—Drs. RICHARD M. PEARCE, O. H. PERRY PEPPER, and SAMUEL GOLDSCHMIDT presented this study and also the patient upon whom the observations had been made. This patient was a boy five and one-half years of age with a history of congenital hemolytic icterus, which had been complicated by a partial paralysis of the left side, loss of power of speech, and otitis media. There was a tendency to localized edema and obstinate constipation together with the usual symptoms of this condition. Two other children in the family had been slightly jaundiced after birth but had otherwise been in good health. The father was said to have had an enlarged spleen and offered a history of exposure to lues, of skin eruption, and of chronic abscess. The Wassermann reaction in the patient had always been negative; however, salvarsan had been administered five times per rectum. The literature showed that in only three instances had metabolic studies in man been made both before and after splenectomy. Two of these were studies of Banti's disease by Umber and the third was a study of pernicious anemia by Minot. In none of these was the study as complete as in the present instance. The first metabolic period ran from the 4th to the 14th of December, 1914, during which time there was little change in the patient's condition. Examination again on January 26, 1915, revealed nothing new. Splenectomy was performed on January 28, and was followed by a satisfactory convalescence. On February 5, the second period of metabolism study was started and continued

for ten days. After comparing the results of their observations during the two periods the authors summarize as follows: (1) A slight positive nitrogen balance before splenectomy was followed by an increased retention eight days after the operation. (2) The output of uric acid showed a decrease of 47 per cent. after the operation. (3) In the period directly after the operation a change in the partition of creatinin and creatin elimination occurred; the total creatinin, however, showed but slight change. (4) Other urinary nitrogen constituents showed no variation from normal, and no change was found in the hydrogen ion concentration. (5) The utilization of nitrogen was good at all times. (6) Fat metabolism was normal. (7) There was a large loss of iron through the feces before splenectomy, followed by a decided decrease (40 per cent.) after the operation. (8) The excretion of urobilinogen and urobilin in the feces was markedly diminished after splenectomy, the amount excreted after the operation being about one-ninth that excreted before splenectomy. Dr. Pearce exhibited the spleen that had been removed and presented the pathologist's report.

Electrocardiographic Tracings in Children.—Dr. E. B. KRUMBHAAR of Philadelphia spoke briefly on this subject and exhibited the cardiographic tracings which he had made. He stated that in studying pathological hearts in young children and in making tracings he had found that there were no electrocardiographic tracings of the normal heart in infancy and childhood and that hence they had nothing with which to compare their findings in abnormal conditions of the heart in children. He had succeeded in getting tracings of the fetal heart, and had records taken just before and just after the cord was cut. These showed that the heart acted much better just before the cord was cut than for a time afterward. At birth there was a preponderance of the right ventricular sounds, and this persisted up to the sixth or eighth week. This preponderance of the right ventricular sounds had been observed in older individuals occasionally and had been difficult to explain hitherto. One of the electrocardiographs was of special interest because when they began to take it there was a perfectly normal, regular interval, and within a few minutes the interval became four times as long. This child later developed heart block and it seemed that they had succeeded in observing it in its early stage.

Inbreeding Experiments with the Albino Rat.—Dr. HELEN DEAN KIND read this paper at the Wistar Institute of Anatomy and Biology, and gave the audience the opportunity of inspecting the rat colony. The inbreeding experiments were undertaken to determine whether close inbreeding altered the sex ratio by increasing the number of males, as several investigators had maintained, and to ascertain whether, as generally believed, this form of breeding necessarily led to sterility, loss in body size, and in constitutional vigor. The experiments were begun six years ago with a stock litter of four albino rats, two males and two females. At the present time there were twenty-one generations of rats. The descendants of each pair had been kept separate and the closest kind of inbreeding had been carried on, namely, the mating of brother and sister of the same litter. In both series environmental and nutritive conditions had been identical. The average rate of males to females in 1,000 stock litters had been found to be 107 males to 100 females, practically the same sex ratio that is found in man. During the first six generations no attempt was made to influence the sex ratio, and in 1,500 individuals belonging to these generations there were 105 males to 100 females. This indicated that close inbreeding alone did not appreciably alter the sex ratio. From the sixth generation on there had been a careful selection of breeding animals. The descendants of the one original pair were designated the male line, those of the other pair, the female line. In the first series every male used came from a litter containing an excess of males, while in the second series, the female line, every female had belonged to a litter containing an excess of females. Each female was mated twice to a brother of the same litter. Following this method the sex records were now complete for nineteen generations. In the male series there had been an increase in the proportion of males, varying from 3 to 42 per cent. above the normal in the different generations; in the female series, there had been an increase in the number of females in each generation, the number of males being from 6 to 33 per cent. below normal. At present no explanation could be offered as

to the way in which this change had been brought about. The sex ratio of a given litter could not be predicted and it was only when a large number of litters were taken that the results cited were obtained. With reference to the body weight of inbred rats, it had been found that during the first sixty days of post-natal life the growth in body weight was practically the same in inbred and stock albino rats, but that after this time the inbred rats exceeded the stock rats in weight at any given age. After 150 days of age inbred males were about 15 per cent. heavier than stock males. In the females there was less difference, the inbred females being about 3 per cent. heavier than the stock females. This result was the more striking since no attempt had been made to breed for body size, although the largest and most vigorous individuals from the litters were selected to continue the series. Sterility had been said to be one of the evil effects of inbreeding, but here the rat seemed to be an exception, for the average litter contained seven young and the records of over 1,200 litters of inbred rats showed the average number of young per litter to be 7.4. In this colony the inbred rats lived fully as long as did the stock rats and appeared to be equally resistant to disease. During the past ten years observations had been made on about 50,000 rats and at present some 3,000 were under observation.

Lobar Pneumonia: The Correlation of its Symptoms and Physical Signs with the Findings of the Röntgen Ray.—Dr. HOWARD HARRISON MASON of New York presented this communication and stated that at the Presbyterian Hospital in New York City, during the past two years, all cases of lobar pneumonia had been x-rayed at least once. Weil and Mouriguard from 300 cases studied by the x-ray concluded that the early shadow was usually triangular in shape with its base always cortical and generally axillary. They stated that they had never seen a shadow entirely central and the shadow was often present before the signs of consolidation appeared, and in some cases these signs of consolidation never appeared. In the present study all cases having fluid had been excluded and this left thirty-seven uncomplicated cases of lobar pneumonia. All of these showed definite shadows, quite dense and uniform, and usually definitely outlined. In every case the shadow was situated so that the consolidation must touch the pleura at some point. The exposures were all made with the children on the back or abdomen. It was believed that the inference was justified that the dimensions of the shadow corresponded to the extension of the consolidation. From the observations made in this study it might be concluded as follows: (1) The consolidation of lobar pneumonia in children began in that portion of the lung which laid just beneath the pleura. (2) A central pneumonia in the strict sense never occurred. Silent consolidations were subpleural consolidations and were separated from the hilum by normal lung. (3) Bronchial breath and voice sounds were dependent upon the presence of a medium of comparatively uniform density from the site of their origin (the trachea and large bronchi) to the point where the ear or stethoscope was applied. These conditions were fulfilled when the consolidated area extended from just beneath the ear to the region of the hilum. Of the thirty-seven cases studied, fifteen showed in the first Roentgenogram a uniform dense shadow extending over almost all of one lobe. The first negative of seven cases showed a medium shadow and it was impossible to tell how deep the shadows extended. In thirteen cases the shadow was lateral and as it developed further triangular with its base standing on its periphery. In other words consolidation seemed to begin at the point anatomically farthest from the hilum, but it might begin along the mediastinal pleura or along the diaphragmatic pleura, but always in a portion of the lung close to the pleura.

Dr. LEON T. LEWALD of New York showed lantern slides of radiographs which were confirmatory of Dr. Mason's. One case of very early pneumonia showed the practical application of Dr. Mason's work. Several slides were also shown illustrating the bronchial tree after injection through the bronchoscope. These had been made with the assistance of Dr. H. D. Lynah and showed that there was normally a dense shadow about the hilum on each side and that this had led to many misinterpretations of radiographs and to the diagnosis of tuberculosis when there was really nothing abnormal in the region of the hilum. Dr. LeWald showed the Roentgenogram of a child who was

taken ill very suddenly and complained of pain in the right lower quadrant of the abdomen. There were other physical signs pointing to appendicitis, but there was very little suggestive of pneumonia. However, it was impossible to tell from the physical signs whether one was dealing with a pneumonia or an appendicitis. The Roentgenogram showed an area of consolidation in the right lung and the diagnosis of pneumonia was made. A definite pneumonia could be made out the next day and the child went on to crisis and recovery. This instance showed the utility of the x-ray for otherwise the child would have been subjected to an altogether unnecessary operation. Another slide also showed the necessity of radiographing a child in the presence of conditions not readily recognized. This child had suffered from symptoms which were thought to indicate the necessity for a rib resection. No x-ray examination was asked for; the operation was done, but without relief. The child was then radiographed and a foreign body, an upholstery tack, was located in the right bronchus, where, upon careful inquiry, it was found to have been lodged for two years. This body was removed by Dr. Nathan W. Green through the bronchoscope by means of an electromagnet. Dr. LeWald showed another lantern slide presenting a wedge-shaped shadow which might easily have been mistaken for an encysted pleuritic effusion, but it resolved of itself, as disclosed by confirmatory radiographs, and this also showed how a mistake might have been made and an unnecessary operation performed.

Studies in Tuberculosis in Infancy.—Dr. CHARLES HUNTER DUNN of Boston presented this study which was made at the new Memorial Building of the Infant's Hospital in Boston. He said that for the past nine months they had made the giving of permission to perform an autopsy in case the child died one of the requirements for admission to the hospital, and that this rule had made possible the present investigation. He reviewed the contradictory evidence with reference to the portal of entry of the tubercle bacilli in children and expressed the opinion that the explanation of these different theories as to the mode of invasion of the tubercle bacilli was due to a variation in the character of the milk supply in different localities, and in the variation in the amount of tuberculous disease in cattle in various parts of the world. He believed that infants could become infected with tuberculosis either by the human bacillus entering through the lungs or with bovine tuberculosis by the bacillus entering through the intestine. The present study, he said, must be taken as bearing on conditions in Boston and the vicinity. Von Pirquet adhered to the view of Ghon that tuberculous infection always showed a lesion at the portal of entry. This view differed from that most generally accepted that the tubercle bacilli in infancy could and usually did pass through the tissues at the portal of entry, and then followed the lymphatic channels, reaching the lymph nodes where they produced the primary lesion. In the present study an investigation had been made of the primary lesion, making a careful examination of the lungs and intestines in each case. In this series of cases the lungs were cut up in the smallest fragments and all suspicious areas were subjected to examination. In all there were twenty-five post mortems and in twenty-two of these a primary lesion was found at the portal of entry. Three cases in which the primary lesion was not found at the portal of entry showed chronic tuberculosis of the bronchial lymph nodes, but none of the mesenteric lymph nodes. The nature of the primary lesion in some cases was such as to suggest that it might easily have been overlooked, and it was possible that in the three cases in which it was not found a still more inconspicuous primary lesion might have escaped notice. Dr. Dunn believed with Ghon that it was more probable that when a primary lesion was not found at the portal of entry, it was overlooked. As to the location of the primary lesion, in twenty cases it was found in the lung and in two in the intestines. If one added to the twenty cases the three in which only chronic lesions were found in the bronchial lymph nodes, one had a ratio of twenty-three cases of infection through the lungs and two cases of infection through the intestines. It was evident that in Boston the most frequent mode of infection was by inhalation from the human source, but bovine infection from milk might occur. The principal lesion in the lung was easily recognizable; in most of the cases there was a circular area, varying in size from that of a pea to a hazel-nut; the

center was caseous but of a greyer color than the yellowish caseation seen in the secondary lesions. In some instances there was caseous softening, or small cavities, and in one instance there was calcification. In a few cases the primary lesion was much larger reaching the pleura and marked by firm fibrous adhesions. Around the periphery of some of the smaller lesions there were numerous miliary tubercles suggesting direct extension of the tuberculous process. In only one case was there more than one lesion of this description. Microscopically, the primary lesion differed from the caseous tubercles and secondary areas, in that the latter, even when the section showed wholly necrotic tissue, the lung structure, the outlines of the bronchioles, and the alveoli were faintly discernible, while in the primary necrotic lesion it always appeared homogeneous. In only one case was there evidence of healing in the primary lesion. However, all the cases were fatal ones in young children with a low degree of resistance. The primary lesion found in the intestine was a tuberculous ulceration, sometimes single and sometimes multiple. They did not differ from the secondary lesions found in several cases. The reasons for believing that these were primary lesions were (1) that only the mesenteric lymph nodes were involved and that there was no tuberculosis of the bronchial lymph nodes; (2) the involvement of the bronchial lymph nodes in twenty cases having a primary lesion in the lung and in three in which no primary lesion was found; (3) the fact that one of the cases was one of a series occurring in that locality, all using the same milk supply, and animal inoculation yielded the bovine type of bacillus. The mesenteric lymph nodes were tuberculous in seven cases in addition to the bronchial lymph nodes, and were involved alone in two cases having the primary lesion in the intestine. There was tuberculous ulceration of the intestinal mucous membrane in seven cases besides the two in which this lesion was considered primary. There were good reasons for believing that these were secondary lesions, because in all seven the primary lesion was found in the lungs, in all the involvement of the bronchial lymph nodes was more advanced than the intestinal lesion and because in no cases in which there was caseous softening cavity formation in the primary lesion was there a failure to find ulceration in the intestine. In the writer's opinion these intestinal lesions were secondary and caused by swallowing tuberculous material from the lesion in the lungs. Many cases showed tuberculous mesenteric lymph nodes without intestinal lesions. This was evidence against the view that the tubercle bacilli were able to pass through the intestinal mucosa without leaving traces of their progress in the form of a definite lesion. Other secondary lesions were found but were mostly of an acute character, a more or less generalized miliary tuberculosis. In nineteen cases a tuberculous meningitis was found which was the immediate cause of death. In thirteen of these the meninges showed small miliary tubercles without evidence of exudation. In only five cases were animal inoculations made and in one of these the bovine type of bacillus was found; the other four showed the human type. The bovine case was known to have had contaminated milk and the primary lesion was found in the intestine. As to the diagnosis, in fifteen of the series there was definite picture of tuberculous meningitis with the characteristic cerebrospinal fluid. Dr. Dunn said he was inclined to doubt if miliary tuberculosis could be diagnosed in infancy unless the brain was involved. The important point was whether the condition could have been recognized before the onset of acute manifestations. There were three points upon which the diagnosis of tuberculosis in infancy rested: (1) The finding of physical signs of tuberculosis in the chest; (2) evidence of tuberculosis as attested by a positive von Pirquet reaction; (3) evidence furnished by the x-ray. In this series the physical signs were positive in fourteen cases, negative in eleven. In four of the fourteen cases d'Espine's sign was the only one found. In the other ten cases there was evidence of consolidation suggestive of tuberculosis. A comparison of the physical signs with the autopsy findings brought out the following points: (1) Acute miliary tuberculosis of the lung without tuberculous bronchopneumonia gave no recognizable sign in the lungs; (2) tuberculous bronchopneumonia usually did give recognizable signs in the lungs; (3) the presence of d'Espine's sign in the infant usually meant tuberculosis of the bronchial lymph nodes, but might not be

obtained in cases in which the glands were found enlarged at autopsy; (4) the primary lesion gave no recognizable signs in the child unless very large and there was consolidation indicating bronchopneumonia. The von Pirquet reaction was present in six cases, negative in twelve and not one in seven. A positive von Pirquet reaction meant tuberculosis in infancy; a negative reaction, however, did not mean that tuberculosis was absent. The x-ray evidence was positive in thirteen cases, in fact in every case in which it was used. There were several cases in which it gave the only positive evidence of tuberculosis obtainable. Enlarged bronchial lymph nodes were made out in most cases.

Experimental Studies and Clinical Value of the Guinea Pig Test for the Virulence of Diphtheria Bacilli.

—DRS. JOHN A. KOLMER, SAMUEL S. WOODY, and EMILY L. MOSAGE of Philadelphia presented this communication, which was read by Dr. Kolmer. He stated that the morphological, biological and tinctorial qualities of the diphtheria bacillus were so distinctive that with comparatively little experience they were readily detected in properly made cultures, and if diphtheria bacilli were found on mucous membranes only in diphtheria and disappeared in a reasonable length of time after the clinical evidence of infection had disappeared, nothing would be simpler or more satisfactory than the bacteriological diagnosis of the majority of these infections. From a practical standpoint, however, the bacteriological diagnosis of diphtheria was greatly complicated by reason of the fact that many persons harbored diphtheria-like bacilli on the mucous membranes, particularly of the nose and throat, that were apparently harmless and compatible with normal health. In the presence of inflammatory changes in these parts following direct exposure to a known case of diphtheria, the presence of these "carrier" bacilli greatly complicated the situation when it was necessary to determine whether actual infection with diphtheria was present or not. Likewise following an attack of diphtheria the bacilli might persist for long periods of time on the mucous membranes even though the patient was in all respects restored to health. Prolonged, expensive, and tiresome quarantine was thus necessary until repeated cultures showed the patient to be, temporarily at least, free from diphtheria bacilli. It was now known that these "carrier" cases, both the convalescent and the person who had never had clinical diphtheria, might carry, virulent or non-circulant bacilli, or both, on the same mucous membrane. It was thus readily understood that some practical and reasonably sure means of differentiating virulent from non-virulent diphtheria bacilli was highly desirable. Before any test could be accepted as sufficiently safe in practical work to regard a carrier as free from danger to himself and others, several important questions must be answered: (1) Could bacilli that were without disease producing powers according to their tests resume virulence and induce disease? (2) Might not bacilli of low pathogenicity produce an infection in a second individual of signs of malnutrition in the way of rickets if they low resistance while causing no apparent harm to the carrier? (3) Might not virulent bacilli gradually lose virulence and later resume full pathogenic powers under conditions over which they had no control? The weight of experimental evidence was to the effect that diphtheria bacilli which had proven non-virulent with every test remained so indefinitely despite prolonged efforts to give them even feeble powers. It was entirely different, however, with bacilli of low pathogenicity; with these passage through animals or from throat to throat among men might readily enough restore a high degree of pathogenicity. It was reasonable to suppose and clinical experience supported the contention that bacilli of low virulence and apparently harmless to the host might be capable of harm in a second individual. The third question was more difficult to answer. Many observers had noted that diphtheria bacilli retained their virulence until they disappeared, regardless of their length of stay. They had found this true in not a few instances. But they had also reason to believe that after a time, the minimum being not less than two weeks, a proportion of the bacilli proved non-virulent when tested by animal inoculation. Whether or not they regained virulence when they passed from throat to throat they had no direct evidence. Most physicians depended upon two or three consecutive negative cultures before discharging a patient as cured, but when one stopped to consider the fallacies of this method it was a question whether a

good virulence test was not to be preferred. Animal inoculation tests had been found of great value in determining the virulence of diphtheria bacilli. Virulence tests in order to be practical and reliable must be sufficiently delicate to detect low degrees of virulence and this constituted the first and important essential; it was also desirable to conduct the test as economically as possible and as speedily as was consistent with specificity and delicacy. The subcutaneous injection of a 250 to 300 gram guinea pig with a culture was found to yield better results than intracutaneous and intraperitoneal injections. The subcutaneous injection of 4 c.c. of a good twenty-four hour culture of diphtheria bacilli on a tube of Loeffler's media washed off with a 10 per cent. normal salt solution was found to yield as delicate and specific results as any method, besides being a test requiring a short space of time for its conduct. A second method yielding excellent results, but requiring more time consisted in cultivating the bacilli in serum dextrose broth for seventy-two hours and injecting a 250 to 300 gram guinea pig subcutaneously with 1.3 to 1.5 c.c. of unfiltered culture. Focal edema and even the slightest evidence of toxemia in the test animal with absence of these signs in the control animal was regarded as indicating virulence, even though the animal did not succumb in the four day period of observation. In classifying the cultures submitted to the virulence tests the types were recorded after the classification of Westbrook, Wilson, and McDaniel. The results of 1,054 tests conducted after this method with granular, barred, and solid bacilli from the throat, nose, ear, and other mucous membranes were shown in charts, an analysis of which showed that the granular types of diphtheria bacilli were found virulent in about 70 per cent. of the cultures from the throat, nose, and ear; barred bacilli were found of equal virulence as the granular types. The long solid bacilli were found virulent in about 42 per cent. of the cultures; cultures of short solid bacilli were found uniformly to possess no virulence. These virulence tests were of the utmost value in determining the potential harmfulness of the solid varieties of diphtheria bacilli because these types were specially likely to be found in the "carriers." In the Philadelphia Hospital for Contagious Diseases, in all instances where the virulence test was negative the patient was considered non-infectious and fit for release from quarantine. These cases had been followed closely and the number of "return" cases had become practically negligible.

NEUROLOGICAL SOCIETY OF NEW YORK.

Three Hundred and Forty-first Regular Meeting, Held Tuesday, October 5, 1915.

THE PRESIDENT, DR. WM. M. LESZYNSKY, IN THE CHAIR.

Case of Cerebrospinal Syphilis.—Dr. E. G. ZABRISKIE presented this patient, a man 39 years of age, a locomotive engineer. In October, 1913, his brother, a railway engineer, was killed in a wreck. This depressed the patient a great deal. He began to be very talkative and his ideas assumed an expansive character. He maintained that a bill should be introduced to Congress making bridge and trestle inspection compulsory. He talked about it and the accident all the time. He became extremely agitated in manner and speech and his hands were so tremulous that he had difficulty in feeding himself. Dr. Gaines, who examined him at this time, said he displayed no realization of the seriousness of his mental condition. At that time he had Argyll-Robertson pupils, unequal in size, irregular in contour, speech somewhat indistinct, knee jerks somewhat exaggerated, a slight facial and manual tremor. He was sent to the Johns Hopkins Hospital where at that time it was learned that he had in addition to the above symptoms a desire to buy tracts of land in Florida and he expected to become rich thereby. In a short time he developed marked insomnia, talking constantly, and was extremely nervous and agitated in his manner, so much so that for a period he was unable to feed himself. His deportment was good and his language proper. Under treatment in a sanatorium, where it was necessary to confine him, he slept well, gained weight, and became quiet. On Feb. 19, 20, and 21, 1914, he was in an elated, over-talkative condition, expressed many grandiose ideas about his future plans which were extremely visionary in character and impossible of execution. He apparently did not realize the seriousness

of his mental condition. Physical examination was the same as that of Dr. Gaines. There was elicited from his past history the fact that he had a primary sore about 15 years ago. The examination at the Johns Hopkins serological department showed a positive Wassermann, in the cerebrospinal fluid, a positive gold chloride reaction, positive globulin, 30 cells. Diagnosis of general paresis was made. He was given, under Dr. Barker's direction, five or six injections of salvarsanized serum, which were followed by a very marked clinical improvement. He was then given neosalvarsan intraspinally by the Ravot method which was followed by sphincter incontinence, spasticity of the legs, and intense pains in the legs and rectum. Root pains were very similar to those at the present time. The mental symptoms had entirely subsided. The patient had been extremely uncomfortable, complaining constantly of pain and stiffness in the legs, sleeplessness, incontinence of urine and feces. He had had three further injections by the Swift-Ellis method and a series of five intravenous injections of 0.5 gm. salvarsan. His blood had become negative, but the cerebrospinal fluid had remained constantly positive. Cells and globulin remained plus. The mental attitude at the present time was that of a man constantly introspective over his sad plight and very discouraged. The physical examination showed unsteady station, spastic gait; left pupil larger than right, both irregular and fixed to light. The facial expression was dull and listless. Reflexes of the arms were slightly increased, and of the abdominals slightly exaggerated. Ankle jerks were present, left greater than right. There was a double Babinski and no ankle or patellar clonus. The serological findings were: blood Wassermann positive; cerebrospinal fluid, positive; cells, nine; globulin weakly positive; gold chloride positive. The case was presented to illustrate the possible consequences of certain methods of administration of salvarsan.

Results of Intraspinal Treatment in General Paresis.

—Dr. HANSON S. OGILVIE read this paper. The cases reported presented at the original examination the classical syndrome of dementia paralytica. All gave positive serobiological evidences of syphilitic disease in the cerebrospinal fluid, and all but two showed positive findings in the blood serum. The average duration of symptoms was one year and nine months, the shortest being six months, and the longest four years and six months. Out of the entire series only five were "socially possible" when treatment was instituted. Twenty-two patients had previously received intensive intravenous and intramuscular treatment during six months to two years, and 8 had had remissions of from two to eight months with relapse. The method employed was a modification of that of Swift and Ellis. The curative serum was of standard strength, prepared *in vitro*, according to a previously detailed technique. Eighteen hundred treatments had shown the serum to be safe and effectual where intraspinal therapy was indicated. In general paresis it was superior to the Swift and Ellis serum. Statistics were as follows: Total number of patients treated 35; average number of treatments given, 21; minimum number to induce a remission, 6; and maximum 14; largest number given to one patient, 42. Salvarsan intravenously and mercury intramuscularly were given systematically, the intravenous treatments being scheduled to alternate with the intraspinal. Three groups of cases were recorded: (1) with complete; (2) with incomplete clinical remissions, and (3) with failure to respond to treatment.

Group I, of twelve cases, or 34 per cent., all had been totally incapacitated for work, eight being insane. Of these nine resumed their former vocations. Biologically, four of the twelve were negative in blood and spinal fluid. Eight still had positive Wassermann tests. There was marked improvement in the health of all. Group II, of fourteen cases, or 40 per cent., all had been totally incompetent. Of these the remissions were incomplete, but rendered the patients socially possible. They were able to live at home and attend to daily functions without help. None of these Wassermans became negative. Group III, of nine cases, or 25 per cent, were counted as failures, clinically and biologically. The question of permanency of results presented itself. No accurate prediction could as yet be made. In true parenchymatous disease of the brain it was impossible to secure a completely negative Wassermann. Where the specific process was confined to the interstitial cerebral tissues the outlook was prob-

ably better. Yet, many cases of remission, occurring without treatment and spontaneously, were on record. Obviously other factors besides the presence or absence of laboratory findings determined the duration of a remission. The value of intraspinal treatment, however, could not be judged by the duration of remissions. No two cases were identical. The method showed better results in a far greater percentage of cases of all kinds, than the older methods of treatment. Here, as elsewhere, the time to treat the disease successfully was in its incipency, before the parenchyma of the cortex had degenerated. Other factors essential to success were care and judgment as to serum strength and frequency of administration. No fixed set of rules was possible. In paresis a stronger serum was indicated. Dosage often extended over many months and should be kept well within the patient's tolerance.

Intraspinal Treatment of Paresis.—Dr. GEORGE AMSDEN presented this paper, which was an attempt to arrive at a practical estimate of intraspinal treatment of luetic disease of the central nervous system. The report was based on sixteen cases of paresis. The treatment was started at Bloomingdale on April 13, 1915, since which they had admitted nineteen cases of paresis. Of these fourteen were treated. Very advanced cases were not considered. Of two groups of cases, each consisting of seven patients, the first were commenced about two years ago, the second group were more recent. Of Group I, five showed a high degree of improvement, and retained it for a year or more, two permanently, and three subsequently relapsing. Of Group II, five attained good improvement, and three of them retained it for considerable time. Roughly then, 62 per cent. attained improvement, but only 12 per cent. retained it. Comparison with untreated cases, carefully noted, had not been made, however, therefore there was no exact criterion. The duration and quality of remissions must be considered in judging the value of results. In about 38 per cent. no improvement was shown, although the patients were not injured by the treatment. Of the 68 per cent. which showed some improvement the remissions lasted from three months to one year and a half. The quality of improvement offered no great interest. Most cases, however, gained insight, in some thoroughly. The prevailing mood was one of seriousness, sometimes slight anxiety, otherwise they were little different from normal well being. A whining depression often characterized the remissions. Untreated cases, on the contrary, showed complete complacency. The advantage, for the time being, to the family, was considerable, but the prolongation of the burden which the patients must ultimately become, must be considered. Evidently intraspinal treatment with salvarsanized serum markedly checked the progress of the disease, at least clinically. In very rare cases it stopped it. Where a temporary improvement was desirable, the method was encouraging. It would be unfortunate if poor permanent success in arresting the disease should discourage physicians from trying it and trying to improve it.

Treatment of Cases of Cerebrospinal Syphilis.—Dr. HENRY A. COTTON of Trenton made this presentation. At the Trenton State Hospital they had been treating cases of cerebrospinal syphilis for over two years and a half, and they had been able to classify three different types; general paralysis, tabes dorsalis, and cerebrospinal syphilis, a mixed type, which was neither tabes nor paresis. The last type showed very marked sensory disturbances, Argyll-Robertson pupils, severe bladder disturbances, but, as a rule, no marked psychosis and they were consequently not committed to the State institutions. Altogether about seventy-five cases had been treated, and at the present time there were twenty-five patients under treatment. The treated cases fell into four groups: (1) arrested cases (11 or 35 per cent.); (2) much improved (7 or 22.5 per cent.); (3) not improved (7 or 22.5 per cent.); (4) fatal cases (6 or 19.5 per cent.). Subsequent observations would change these figures somewhat, but they would not vary to any great extent. Dr. Cotton's experience had been similar to Dr. Amsden's with regard to relapses and several of his most promising cases at the beginning of the treatment (some in spite of persistent treatment and others from the fact that they were removed and treatment discontinued), had shown a tendency to relapse. In spite of the fact that certain cases had relapsed, he thought the work had been extremely encouraging. An important point to be emphasized was that the patient must be treated in the incipient stage if good results were to be accomplished.

The length of the duration was not always the index of the severity of the process, as some of the patients, in which the duration was two years, had done remarkably well. In order for the treatment to be effectual it had to be administered early in the incipient stage. The question was, could this incipient stage be diagnosed by the general practitioner or the consulting neurologist or psychiatrist. He thought the answer was in the affirmative. There was no reason why incipient paresis could not be diagnosed as well as incipient tuberculosis or any other disease, where the treatment must be early to be effectual. Seventy-six per cent. of patients with paresis committed to the State hospitals were insane beyond any therapeutic help, which left 25 per cent. who could be much benefited by treatment, and often the progress of the disease could be materially arrested. The symptoms of incipient paresis should not be difficult to recognize and in the records of a large number of cases, there were shown definite periods, from three to ten years, before they were committed to the hospital, when the patient had evidences of some neurological or psychic disturbance. Sensory disturbances were shown, such as dizzy spells, delirious episodes, mild depressions, neurasthenic episodes, irritability, change of disposition, general inefficiency; and on the neurological side, paresthesias, bladder disturbances, defects of vision, changes in the pupils, changes in writing and gait, high blood pressure without apparent cause. When such symptoms were present in a man of middle age or even younger, especially with a history of previous syphilitic infection, a thorough examination of the blood and spinal fluid should be made. These symptoms usually occurred during the incipient stage of paresis and might well correspond to the invasions of the spirochetæ in the meninges. It was possible that even with a positive cell count, increased globulin, positive Wassermann reactions in the blood and spinal fluid and a positive gold chloride reaction, that such a case might not develop paresis, but chances were against this assumption, and such a patient should certainly be treated with salvarsanized serum intraspinally, or mercurialized serum. In two patients, in whom the most prominent symptom was high blood pressure, one was suffering from depression, ideas of poverty, but was attending to his work. When examined he had stiff dilated pupils, the eye grounds suggested specific trouble, and lumbar puncture revealed plus cell count, increased globulin and positive Wassermann in spinal fluid. The blood Wassermann was negative. This patient had been successfully treated, and biologically and clinically he presented at the present a normal picture. The other patient was a locomotive engineer who was apparently perfectly well and in the routine examination he was found to have a blood pressure of 220. He had a history of syphilis five years previously. Lumbar puncture revealed 89 cells per cm. 4 plus globulin and 4 plus Wassermann in the spinal fluid. The blood serum was negative. He had no headache and no neurological disturbance, except that the pupils were somewhat sluggish. While such cases could not be called paresis, Dr. Cotton was fully convinced that if untreated, such patients would, within a year or two be classified as such. Thus they were considered incipient. The general practitioner should be educated to recognize the first symptoms of such a stage. In the State hospitals the disease had progressed too far to be benefited by treatment. In regard to methods of treatment: The Swift-Ellis was familiar and gave as good results as any. The criticism that the amount of salvarsan could not be estimated had been met by the Ogilvie method where a standardized serum was used. The cerebral puncture of Wardner had much to recommend it, but it was not likely to produce results where the Ogilvie or Swift-Ellis method had failed. Wardner's method might be more permanent and might not tend to relapse so much. The method of Byrne, mercurialized serum, might prove just as efficient as salvarsanized serum, and the increase in cost of salvarsan increased the necessity of a substitute. Two tabetic cases treated by this method did not react well; one died; one recovered and did well later. Recently he had gotten most encouraging results by this method. Its small cost was in its favor, especially for dispensary cases. The method of Hammond and Sharpe, ventricular puncture, had no advantage over the method of Wardner. A sixth method was their own modification, whereby they used the standardized serum of Ogilvie for cerebral puncture, and mercurialized serum for both cerebral and intraventricular puncture. It had not been used long.

enough to give a final report on. They had not been able to prevent relapses. Some patients had done well for six months or a year and had then relapsed in spite of treatment. In some the biological reactions were positive, in some negative. A persistently strong Wassermann reaction in the spinal fluid was a bad prognostic sign. Treatment should be continued till the Wassermann was negative. Most patients showed a decided improvement after four or five treatments; the cell count dropped; the globulin became negative, and the Wassermann much reduced; clinically also there was improvement. With an uninfluenced Wassermann, however, the prognosis was bad, even with clinical improvement. They had reduced the gold chloride test in many cases. The intraspinal treatment was not dangerous. Eight hundred intraspinal injections had been given and in only three were there irritative effects. These cleared up in a day or two, but they had severe pain. The fact that they had been able to produce remissions in 33 per cent. of cases with treatment, as against 4 per cent. without, warranted the feeling that the treatment was worth while. The treatment improved the physical condition and prevented the patients becoming useless and bed ridden. Interruption of the treatment was dangerous, and regular treatment produced the best results.

Dr. H. C. SOLOMON of Boston stated that when they started this work three years ago at the Psychopathic Hospital, Dr. Myerson had charge and he published his results. Later, Dr. Solomon treated a certain number of cases intraspinaly and the results were not particularly favorable and after a few months he became discouraged, as only one case out of the series recovered completely, serologically and clinically. They then adopted the ideas of the difference between the meningo-vascular syphilis and the syphilis centralis, of Head and Fearnside; between the mesenchymal and the parenchymatous variety of Alzheimer. In the former type they expected improvement by treatment. They felt unable in many cases to differentiate between general paresis and Fournier's syphilitic pseudo-paralysis or Binswanger's postsyphilitic dementia, and therefore felt that treatment was indicated. The method of treatment was salvarsan intravenously, twice a week and dosage varying from 0.6 to 1.2 gram. Some cases also received mercury salicylate, intramuscularly, once or twice a week with potassium iodide, grains 15 to 100, three times a day. In a recent series of nine patients treated intravenously, two became much worse, seven were now able to go about their business, one woman had a baby who had never gone beyond the fifth month of pregnancy without miscarriage. Two of the cases, indistinguishable from general paresis, had been serologically negative for many months and had made clinical recoveries. It should be remembered, as Alzheimer had pointed out, there were two processes in general paresis, a meningitic and a true parenchymatous degeneration with cell atrophy. This cell destruction could not be repaired, but many of the symptoms were due to meningitis and not to primary cell degeneration, and a good deal could be done to cure the meningitis. One early case, after having considerable treatment, died, and at autopsy, showed no evidence of meningitis in brain or cord. Microscopically there was but very slight perivascular infiltration, but marked parenchymatous degeneration. Clinically the case was typically paretic. Oppenheim and Westphal stated that in cases that improved under treatment they had to change their diagnosis of paresis—if they improved they were not paretics. In regard to cases serologically negative, Nonne stated that cases that were serologically negative were not cases of general paresis.

Dr. I. STRAUSS of New York said he thought this discussion was rather a fruitless one. They were not exactly sure of their ground. They had not the statistics, the biological tests, over a long period of time, to compare with present cases, no real scientific basis upon which to form judgment. Dr. Strauss knew that Dr. Cotton could make a better diagnosis of paresis than he could, but he did not think he would call the engineer, with high pressure, a paresis case. He had had such cases in the hospital with no sign of paresis. He had had a boy of 15 with blood pressure of 240 with 3 plus Wassermann in the spinal fluid, but that was a case of congenital syphilis, and no one would consider it a case of paresis. He would also take exception to the case of the patient who was depressed, but in whom the biological findings were positive, as being more than a case of cerebral lues. From his standpoint that was not paresis. In regard to the tabetic cases of Dr. Cot-

ton, why form any judgment regarding the efficacy of the method because tabetic patients could walk? Fraenkel taught tabetic, bedridden patients at Montefiore Home to walk. It looked like a miracle, but he accomplished it. At one time they stretched their cords to make them walk. All kinds of treatment could bring results in tabes, even applying silver nitrate to the urethra was effectual. Another point was that other kinds of treatment than salvarsan had given results in paresis, as good, if not better than those shown to-night at Wagner's clinic. Pilcz treated paresis with tuberculin injections combined with mercury. He reported in 1911 that of 86 cases treated, 23 were able to return to work. In April, 1912, he reported that of the cases treated in 1911, 46 had died and of the 26 living, 10 were attending to work. If the presence of a positive Wassermann in the blood and spinal fluid in a patient who suffered from headache, was to be regarded as incipient paresis, then we had to consider every case of lues in the secondary stage as belonging to this category. He was certain that most authorities would consider this as too extreme a standpoint, therefore the difficulty in diagnosis was another factor which rendered the discussion futile.

Dr. BERNARD SACHS of New York said he did not think they could confine themselves to general paresis. They could not exclude cerebrospinal lues; they must refer to lues of the central nervous system. Every form of general paresis was lues. They must speak of this treatment in its bearings upon the kind of lues of the central nervous system, especially these cases of assumed general paresis. In listening to the clinical histories this evening, as presented by Drs. Zabriskie and Cotton, some of them might have disagreed with the diagnosis of paresis, but all could agree that they were lues of the paretic or tabetic type. In his work with associates in hospital and in private work, he was among the first to advocate intraspinal treatment. Since that time he had become more indifferent, and had come to feel that the method had been unduly pushed. The question was whether more was accomplished by this intraspinal method than by the intravenous. The intraspinal method was more difficult and more likely to lead to serious complications, and had been followed at times by disastrous consequences. He felt that he had seen as great and satisfactory improvement follow upon intravenous therapy as upon intraspinal. They had shown that very little salvarsan was found in salvarsanized serum, and that little was accomplished by that method. Almost any injection had been known to change the cell count and globulin. He had no fault to find with the Swift-Ellis or the Ogilvie method. They had been most carefully studied. They had also to determine whether more had been accomplished by these than by former methods of treatment. A patient had been referred a year and a half ago from the Middle West. He had all the mental and physical symptoms of general paresis. He had had six intravenous salvarsan injections and the result was that he had improved sufficiently to be competent to undertake management of a large commercial concern. All that was noticeable was a slight exuberance, an undue optimism, but yet the man was not cured. He was merely in a remission and would sooner or later relapse. There was danger of attaching too much importance to remissions. The matter was an extremely difficult one. Perhaps there were more cases of remission now than formerly. The period, one or two years, was too short to speak of the cases as really cured. One suggestion to the larger hospitals, he would make, the difficulty of getting salvarsan would increase, and the opportunity was at hand to compile very careful statistics as to the results of treatment in 1915-16, as compared with the salvarsan results of 1913-14. He did not believe that slight changes in the cell count were very important. "Cured" cases must not be only biologically cured, but clinically cured. The latter was of more importance. He believed with Dr. Ogilvie that many more cases were made socially possible with treatment, but he was not inclined to look upon these as cures, although the results were, in some cases, encouraging enough to warrant the treatment. Personally, Dr. Sachs said, he would continue to give his cases most thorough intravenous treatment.

Dr. WALTER TIMME of New York said that he had seen some of the cases reported by Dr. Ogilvie, which showed certainly remarkable improvement. Dr. Sachs had mentioned that he had obtained as much improvement with the intravenous method, and stated that it would do less harm than the intraspinal with salvar-

sanized serum. In the past six weeks Dr. Timme had seen three cases that had had absolutely no treatment for one year to eighteen months. At the beginning of this time, the spinal fluid examination had shown from 16 to 18 cells, Wassermann positive, and globulin in excess in each case. They had had no treatment of any kind during the entire year. Within the past six weeks their fluids had been again examined by competent laboratory workers, and the findings had been returned absolutely negative, that is, there were no cells, Wassermann negative, no globulin. So it could be seen that intraspinal treatment, intravenous treatment, and, in a few cases, no treatment at all, produced similar results. Nonne, in Hamburg, had made similar observations on his cases.

Dr. D. M. KAPLAN said that general paresis was a type of cerebrospinal syphilis that could not be cured. The patient would be brought back. He appreciated what Dr. Solomon said as to the stubbornness of general paresis. One could only influence the meningitic phenomena, but could not repair dead cells. Dr. Cotton was more enthusiastic than the other speakers. He quoted a few cases with remarkable remissions, but he did not call them complete cures. He had spoken of a plus Wassermann without clinical manifestations. Whether that was general paresis Dr. Kaplan could not say, but when one said syphilis of the central nervous system, it could be included. General paresis was incurable and the others were more or less curable as Dr. Sachs had said. In Ogilvie's cases, four out of thirty-five were complete cures and remained in good health. That was a small percentage. The cases were very strongly treated, intraspinal, intravenously, and intramuscularly. He did not believe that one could obtain more than temporary remission, from one month to three years.

Dr. COTTON of Trenton, in closing the discussion, said that he felt he could add very little to what had been said. Most of the criticisms which had been raised had been answered in his article on the treatment of paresis, now in process of publication in the *American Journal of Insanity*. Question had been raised as to the diagnosis of some of the cases presented in the demonstration. Because one or more of the biological reactions might be absent, it was no reason to question the diagnosis of paresis in certain cases. To one who had spent 15 years in a State hospital in almost daily contact with paresis and with the opportunity of making autopsies and studying the brains in a large majority of cases observed during life, questioning the diagnosis by one who had given little, if any, time to the study of paresis seemed somewhat presumptuous. He would answer Dr. Sachs' criticism that one should study the remissions of untreated cases of paresis before one considered remissions due to treatment by stating that a number of studies had been made on this subject. In the State hospital, one found, in the 127 cases admitted over a period of seven years, that the number of remissions in paresis, where the cases were accurately diagnosed by means of lumbar puncture, were at the most only 4 per cent. The question of remissions, had, he thought been thoroughly treated in the article mentioned above. As his figures corresponded to those of Dr. Ogilvie (33 per cent. and 34 per cent. of remissions), as a result of treatment, he thought the question was answered as to the relation of remissions to treatment or no treatment. He still insisted that the question of paresis should be determined by the effects of treatment, that is, even though the patient had all the clinical signs of paresis and the positive biological findings were arrested by treatment, such a case should not be considered some other form of cerebral lues, merely from the fact that the process had been arrested. The argument would be the same as to say that a person suffering from incipient tuberculosis had never had tuberculosis, because the disease was arrested. The cases were similar; it was absolutely necessary to treat tuberculosis in the incipient stages, in order to obtain results. It was fallacious to condemn the treatment of paresis because we could not cure the end stage. He had not found, with Dr. Sachs, that lumbar puncture was a dangerous procedure. In only three cases out of 800 injections had they had irritative effects. He considered intravenous injection of salvarsan attended with more danger than intraspinal. In certain cases of myocardial trouble an intravenous injection might readily prove fatal. This had occurred, Dr. Cotton said, in two patients in his experience. He never had given a full dose of salvarsan intravenously for the first time.

Therapeutic Hints.

Throat Paint.—The following is recommended for the sore throat of acute pharyngitis:

R Glyceriti acidi borici.
Glyceriti acidi tannici.
Glyceriti acidi carbolic, āā ʒj.

M. Sig.: To be painted over the fauces and pharyngeal mucous membrane.—*The Prescriber*.

Frostbite may sometimes be prevented by thoroughly greasing the feet and socks with an animal or vegetable oil; this is especially useful when the feet are wet with melting snow and slush.

Arsenic and Potassium Iodide in Chronic Bronchitis.—Wilcke has found this combination extremely effectual in cases of chronic bronchitis, especially in the aged. His method is to give 2 drops of Fowler's solution three times a day on the first, third, and fifth days, alternating it with a 5 per cent. solution of potassium iodide, of which 15 drops is taken three times a day on the second, fourth, and sixth days, and so on. Each of the drugs is taken in milk after meals. Larger doses are liable to derange the stomach.—*Medizinische Klinik*.

Muscular Rheumatism.—

R Ammonium chloride, ʒi.
Extract of cimicifuga, ʒii.
Syrup of acacia.
Cherry-laurel water, āā fl. ʒi.

M. Sig.: Teaspoonful four times a day, after meals and at bedtime.—*Anstie*.

R Tincture of iodine.
Tincture of aconite root, āā ʒii.
Tincture of opium, ʒss.
Chloroform liniment, ʒiii.

M. Sig.: For external use.—*Bartholow*.

Stomach Cough.—This begins usually late in the day and lasts well into the night, interfering with sleep. The following may be given:

R Aluminis, ʒss.
Potassii bromidi, ʒjss.
Syrupi tolutani, ʒiij.
Aquæ carui, q.s. ad ʒiv.

M. Sig.: One teaspoonful every hour, beginning at 4 P. M.; or the following:

R Aluminis, ʒss.
Tincturæ belladonnæ, ʒss.
Syrupi pruni virginianæ, ʒiij.
Aquæ menthæ piperitæ, q.s. ad ʒiv.

M. Sig.: One teaspoonful every hour after 4 P. M.

Quinsy.—Faulkner recommends the following as a cleansing gargle in tonsillitis: Essence of peppermint, 5 minims, in 4 ounces of a saturated solution of bicarbonate of soda.

Acute Coryza.—

R Dried suprarenal gland, gr. v.
Menthol, gr. iii.
Camphor, gr. x.
French chalk, ʒss.
Powdered acacia, ad ʒi.

M. Sig.: Use as snuff or apply with a powder blower once or twice daily.—*Faulkner*, "Tonsils and Adenoids," 1915.

Palatable Castor Oil.—The taste of castor oil is effectually disguised in the following mixture:

R Olei ricini, ʒss.
Olei caryophylli, ʒij.
Pulveris acaciæ, ʒiss.
Syrupi zingiberis, ʒij.
Aquæ menthæ piperitæ, q.s. ad ʒij.

THE TOBACCO HABIT.*

By ROBERT AGEE, M.D.,
NEW YORK.

SENIOR SURGEON ST. LUKE'S HOSPITAL.

IN this society of a small group of men of wide experience, we should be able to give unprejudiced thought to observations we make daily, on a subject of such medical and social importance as the one I have chosen.

Physicians are natural observers of details, and tonight we should not tincture our views, by our prejudice for or against tobacco, because all of us either are smokers or have smoked and given it up. The world looks to our profession for advice—not reform.

If one asks of a librarian for works on tobacco, he may ask you, "For or against?" It is not in that spirit we will consider the subject. Taking sides is not called for here! We will consider only the *fact* of so widespread a habit; and, *why* we smoke.

For more than a generation fallacious claims of its vicious effects in stunting body growth, causing mental imbecility, moral turpitude, impotence and nerve wrecking have been rife. These hoped for deterrents issued by moralists and clergymen have been a thousandfold neutralized by lurid advertisements of commercial monopolists. It is fair to admit with Towns that "Smoking confers mental satisfaction; it seems to give one companionship when one has none; . . . something to do, when one is bored; . . . keeps one from feeling hungry when one is hungry; . . . and blunts the edge of hardship and worry."

To my mind its virtue both for good and evil lies in the fact that it is a stimulant. Grant that it is also an irritant, its essential quality is stimulation. There are practically four strong stimulants to which civilized people are addicted—alcohol, coffee, tea, and tobacco. All are used from the poles to the equator. Alcohol, in one form or another, meets the needs of every nation for a quick, diffusible stimulant. Its abuse is its only curse. Coffee, tea, and tobacco meet an equally wide call for a mild, innocent stimulant. Either of these is also too easily subject to abuse.

Most habitual users of tobacco will say, "Why call it a stimulant, for it *soothes me*?" That is the keynote of its action! When one has come to the end of a laborious day's work; when one has known the fatiguing strain of holding a prolonged surgical clinic, or the confined work of the laboratory and classroom, or experienced the exhaustion of ministering to the sick, hours upon hours, one easily finds

the fatigue of nerve and brain soothed by the spur of a cigarette or pipe. That is stimulation. It is practically true that one may have better stimulation by a brisk walk in the glorious out-of-doors, with oxygenation of the impurified blood, but through ease and simplicity the brief cigarette smoke has become a habit, with those who rely upon it. If one has never tried it, one never misses it. Of all the stimulants, tobacco, introduced the latest into civilized communities, has, in its use, spread the fastest, partly by natural demand, largely by alluring advertisement.

Of the other two stimulants, tea and coffee, the best testimony of their relative merits was made to an inquiry of mine to Admiral Peary: "Why do you not use coffee instead of tea for the rations of the polar explorers?" He said that hot tea gave the necessary stimulus against the fatigue of labor and the cold, and soothed as well as stimulated, whereas coffee would be so stimulating to their nerves, that with the added effect of intense cold to do their work, the men would exhaust themselves by doing more than they could endure, and be soon worn out under too exciting a stimulus. On the other hand, in tropical countries, where heat induces laziness and represses work, the nervous energy, whipped up by coffee is needed to combat effectually the enervation of climate, and to accomplish adequate work. Hence we see drinking of large quantities of strong coffee in hot countries, and corresponding consumption of tea in cold countries like Russia, Japan, and North China. Similarly, tobacco is heavily used in hot countries like Cuba and Spain to combat the somnolent effect of heat.

Our own climate represents the temperate, so-called "intellectual belt." There is here little need of the excessive activity of mind and body to be stimulated by tobacco. Yet, we have become so addicted to it during three centuries that it has been one added cause which produces a nervous over-activity, which is, to a certain extent, hurtful and degenerating. We see this in the rush of competitive business which amounts almost to a frenzy with commercial agents and warring business houses. Excessive smoking during work is not a delusion when men claim that it clears their brains, and keeps them active. It is like the Scotchman's snuff. If one analyzes the result, however, one can see that the false energy is as abnormal as the whip lash to a horse, and in the end hurtful. On the other hand, one sees numerous high officials in corporations of national importance, who think their weighty responsibilities are best met by cool, clear brains and natural balance of judgment, unwarped by stimulants, either alcoholic or tobacco.

The question must often come to the devotee of tobacco, "Is the pleasure or benefit at all commensurate with the bad effect of using tobacco?" It is fair to say that medical experience shows that the

*Read at a meeting of the Practitioners' Society of New York, Dec. 3, 1915.

farther we get away from natural life, the more it is clear that nature exacts a penalty. Youth has a surplus of energy, is tireless, and unable to judge fairly of the right and wrong of the effect of tobacco; but the very young boy, or the system of a man past middle life, is a more sensitive index, and here we often see the toxic effect of nicotine. There are very few boys in their first experience with tobacco who are not nauseated, dizzy, faint, pallid, confused, and afterward depressed. In later life also, excessive use of tobacco in any form creates, at times, palpitation, indigestion, vertigo, and confusion of mind. I am told training in high athletic competition requires abstinence from tobacco. Every man of us has recognized "tobacco heart" and vetoed smoking until improvement. It has not taken three centuries to find out the deleterious effect of tobacco using, for tirades have been periodical and vituperative since James I opposed it with his so-called "Counterblasts" after Raleigh introduced it to his Court. Even in France after a hundred years, it was said, "No one in France but what took snuff." Its abuse only has been the cause of condemnation. While in the semi-tropics where Columbus first found nations enjoying it, it was natural, indigenous, and desirable, it was deleterious when imported into cooler countries like our own. Insofar as it was unnecessary, it became harmful.

The word "habit" as applied to tobacco implies that it is to be classed with drinking, treating, spitting, chewing gum, and varying customs, not essential to life, but incidental. Curiously enough this general taking to tobacco is but three centuries old, and has gone through changes of fashion, which is the best ground for hope of its ultimate diminution. Smoking moderately was followed by snuff taking, then by chewing, then by "dipping," and all these having been tried and found unsatisfactory or objectionable, have at last been succeeded by *violent* smoking, if I may so speak, and this in turn is already declining. From general testimony it would seem that meerschaum pipe smoking is unfashionable, briarwoods are less and less used, and the cigar and cigarette are left alone in an undisputed field. With many advantages, the cigarette is now dominant.

It may be admitted that in any form tobacco exerts the same influence. It stimulates the body forces for a short while, and is followed by a degree of depression recognized in any sensitive person and calling for another cigarette or cigar, and another to follow that, as the evanescent effect passes away. The pleasing stimulation is so gratifying that its subtle power steals on one, and one indulgence follows another in rapid succession so that the blood is surcharged with nicotine before one is aware of it. We all know, after a period of abstinence, how we feel when we take it up again. The heart palpitates, head throbs, and the tongue next morning has a fuzzy, burnt feeling where the hot tobacco smoke strikes the surface, in contrast to the clean natural tongue of health.

This gives the clue to the terrific charge against tobacco in causing cancer of the tongue and throat. Last July I published a review of one hundred cases of cancer of the tongue and mouth taken from my private notes during fifteen months where the cause was searched for. I demonstrated that nine-tenths of the patients were inveterate users of tobacco. Thirteen cancers inside the cheek were all found in men who chewed, or had chewed. The others were inveterate smokers. I was amazed at the

demonstration. Letters afterwards came to me, such as one from a man whose mother had died a terrible death from cancer of the tongue. He knew his mother had chewed cigars—three cigars a week—for many years, beginning on account of a toothache. His physician assured him the habit had nothing to do with her disease; it was impossible for tobacco to cause cancer, "and that most old people died of cancer anyway." Dr. Halsted of Johns Hopkins Hospital wrote me of a case which had first come to him, like one I had quoted, of terrible cancer caused by rubbing snuff on the tongue, or "dipping."

During the last six weeks I have been consulted by ten patients with grave cancer of the throat or tongue, every one of them heavy smokers, that is, from ten to twelve cigars daily. One man said fifty pipes a day would not exaggerate. He was one of the finest types of Spanish gentlemen, otherwise unsurpassed in health and physique, but with an advanced cancer of the tongue and floor of the mouth—a hopeless condition. One man boasted that he had always smoked cigarettes only, a pack a day of all-tobacco cigarettes, ten in a package. It was difficult to convince him he was the victim of this pleasant habit, but he was beyond saving—a nice chap, poor fellow! One handsome woman had beginning epithelioma on the tip of her nose, with a seborrheic eczema along one nostril. She smoked cigarettes constantly. With a light radium treatment and abandonment of tobacco her nose was perfect in six weeks. Somehow or other it seemed to me she was very happy to be told to stop smoking. It had been a late habit in her life, and a concession to the custom among a group of her lady friends, in diplomatic society especially.

As a habit, indeed, my experience has been to find very rarely a man or woman who cannot easily abandon tobacco, especially people of mature years. There is no drug habit which so lightly holds its victims. It is essentially a social habit. It is fostered by association with others who are smoking, or with certain places which suggest it, or by advertisements thrusting themselves in the faces of the tempted. Every journal, illustrated paper, newspaper, signboard, or one's very morning mail brings alluring pictures of a face of extraordinary cheerfulness pulling on a pipe, or an Oriental woman of surpassing attraction giving the tobacco a name, or appealing to patriotism and the necessity of tobacco to soldiers in the trenches. One of the most beautiful views of our noble Hudson above Grant's Tomb is wholly obscured by a huge house-top advertisement of a so-called "America's greatest cigarette."

The push of commercial monopolies is spreading the wider use of tobacco over China and Japan with alarming rapidity. Twenty-five years ago the gentle art of smoking in Japan was limited to the dainty ceremony of filling a very tiny bowl of an artistic pipe with a bit of the mildest golden thread tobacco; almost an aroma rather than smoke came from the three puffs that consumed all the bowl would hold. The ceremony was universally a light accompaniment of conversation. There would be five minutes of the latter and without interruption, a minute or two to open the ornate pouch, extract a pinch of tobacco, press it into the bowl. This would be held in readiness indefinitely, until conversation, which was the essential, permitted a slight interruption to tilt the pipe bowl over a small bit of glowing charcoal perched on a little mountain of ashes in a cunning dish. Following the

three dainty puffs, a long interval with more chat before the ashes were knocked out of the bowl into, possibly, a bamboo ash receiver. Then another wait. No hot smoking pipe bowl filled in rapid succession. The gentle art of smoking was a pleasing accompaniment of conversation. This seemed to me was the refinement of smoking.

By contrast, we see a group of men in our country sitting about a fire after dinner, armed with long, black cigars (each one would equal the strength of three or four days' smoking for a Japanese). Our friends keep time to their sentences by pulling hot smoke into their mouths as fast as they can for half an hour, inhaling meanwhile the fumes of others in a dense, cloudy atmosphere. Is it any surprise that next morning they find their clothes reeking with stale tobacco smoke? To occupy the same time some prefer to burn three or four cigarettes—always the same *hot smoke*. If we *must* smoke, why can we not learn to use mild tobacco, small cigarettes and infrequently. It is the amount of tobacco and the hot smoke that are responsible for the wrecks of young manhood we see. Even the dainty Japanese has been much corrupted by the seductive cigarette, and has the yellow finger tips and restless manner of the habitué.

From the plantations of Cuba and Virginia are spreading influences which are progressively more and more baneful, as the tobacco habit increases. A million and a quarter acres of the richest land given up to cultivating the plant, for which our country spends annually more than a billion dollars to send up in *smoke*—a large and costly tribute to the habit.

Fortunately, it is a habit that can be easily given up. When fashion dictates, its decline will soon follow. Already one sees more and more men enjoy each other's company after dinner without smoking. Conversation seems even more worth while when men are not artificially put at their ease by after-dinner cigars, which would seem to level up the ordinary man to the type of higher intellectuality by occupying his hands in smoking and giving him an undue sense of importance. *Pari passu* with the recently demonstrated deteriorating influence of alcohol in all nations, followed by a decline in social use of liquor and wine, we all have noted the growing feeling against tobacco. In business there have been scores of mercantile houses, notably in Western cities, who have prohibited cigarette smoking as far as possible, and discouraged its use by clerks and employees. Efficiency has been increased, and the morale of employees improved by it. In schools accumulated statistics show the grading of boys, smokers of cigarettes and non-smokers, gives a large percentage in favor of abstinence. This seems to be more universal in colleges and high schools, the more widely this subject has been investigated. Higher averages of work, less delinquency, more prize men are everywhere found.

I cannot do better than commend the reading of a small book comprehending this vital subject and giving much statistical information, lately written by Prof. Bruce Fink of Miami University, whose ripe experience and unbiased judgment lead him to very strong and sane views of the detrimental influence of cigarette smoking on the adolescent.

Fortunately, it is, as remarked before, a habit so easily surrendered that I have never seen a man in middle and late life especially, who has not immediately responded to my advice that he must be a quitter. Scores of men I have known to throw an

unfinished cigar into the fireplace and say, "Never again!" Occasionally one begs to be allowed to try it a little, but when no compromise is permitted his will is strengthened and he braces up to the final complete decision. In all cases of malignant growth in the mouth, or of ulceration, or precancerous leucoplakia, or smokers' tongue, it is absolutely useless to treat the case, when the irritation of tobacco using continues. Indeed, I have seen great numbers of mouth cancers which had been irritated and increased not only by the persistence in tobacco, but by an added irritant like nitrate of silver, which does more harm than good in mouth cancers.

The resolution to stop smoking in boy cigarette fiends is not as easy as in men. The boy's inexperience with serious matters of life makes him less amenable to logic, so that unless he has great respect for his seniors, he is less impressed by facts. It therefore becomes necessary to invoke the psychological effect of companionship, a mouth wash, and tonic, which works very well when a crowd of boys resolve to stick together and help each other.

In the Western states, Kansas, Illinois, Wisconsin, California, and others, great strides are being made in self-control of the hurtful habit. Notably in Los Angeles an anti-cigarette clinic is conducted by the city, to which clamoring mobs of boys and men go on certain days to get their tonic treatment. It is said to make the taste of tobacco repugnant after five or six treatments. The master of juvenile delinquents who started this clinic found that nine-tenths of those brought before him were cigarette fiends, which had much to do with their depravity. This has been the growing and universal experience with social workers and in juvenile courts the country over. The tobacco habit, thus early initiated, leads to lounging, bad association, deception, lying to parents, stealing to buy cigarettes, thirst for stimulants to match the biting stimulation on the tongue which water is inadequate to quench—all of which is succeeded by lassitude and reaction, requiring repeated stimulation by tobacco, and thus the vicious circle.

We all take our smoking very seriously, as if it were a necessity. On the contrary, it is a luxury, and an *indulgence*; a luxury which many smoking men can ill afford (for some it would represent an annual premium on a good life insurance); an indulgence that is never health giving and often baneful. As it is only a habit, and as we are able to recognize the earliest signs of its ravages in the mouth, it is a sacred duty to stop all tobacco for patients so afflicted. Insurance statistics show that sudden deaths at about fifty years of age are more common among those who use tobacco and spirits heavily—about an equal toll from both classes.

The stand taken by many against tobacco is an unpopular fight. The frontiersman sneers at the tenderfoot who refuses whiskey and a chew, with the remark, "Don't drink? Don't chew? What do you do to smell like a man?" The college undergraduate is invited to attend a "smoker" and is initiated in a reeking atmosphere of tobacco. Yet, at West Point, smoking was prohibited in 1891, and fifteen years later the summary of medical records shows the great advantage in work and discipline. In college a group of men subjected to ergograph tests during abstinence and again after four days' smoking is said to have shown a loss of forty per cent. muscle power. In try-outs for football squads it is said that half as many smokers as non-smokers are successful.

The public recognizes already the obnoxiousness of many forms of tobacco using. The foul cuspidore is out of date; once a necessity, and within our memories a subject for ornamental devices for the drawing room, like bronze turtles whose backs flew up for use when one stepped on the tail—now it is seen only in Pullman cars and ordered out by most ladies before they will sit in the compartment. The wave of reaction is fast showing and medical testimony only is needed to help the coming generation against overindulgence.

Woman's voice against it seems likely to fail in achieving what it did against the spitting menace in the streets because the young women of to-day are imitating the men in companionship of the cigarette habit. It is rather disturbing to see beautiful gardens strewn with cigarette butts among the roses, thrown there by fair hands.

The singer's voice is impossible of its best in an atmosphere of smoke.

I have seen a great painter affect a style of painting so coarse that it shocked his friends, and was evidently due to transient indulgence in unlimited cigarette smoking. His painting was full of the nicotine effect.

Taken all in all, we medical men see and condemn heavy use of tobacco, yet we indulge a little for reasons given and stop when we feel it wise. Our advice to clients will be more severe than our practice perhaps, because of what we know, but we owe it to them to uncover the truth.

13 WEST FIFTIETH STREET

AN ENZYME THEORY OF CANCER ETIOLOGY.

By LEVERETT DALE BRISTOL, M.D.

UNIVERSITY, N. D.

PROFESSOR OF BACTERIOLOGY; DIRECTOR, STATE PUBLIC HEALTH LABORATORIES, UNIVERSITY OF NORTH DAKOTA.

CANCER consists of an abnormal growth composed of epithelial cells which are reproducing themselves rapidly, continuously, and atypically. What is the cause of this excessive atypical cell reproduction? The writer began a study of this problem about four years ago, and in 1913 an article¹ was published which expressed his first ideas on the subject. At that time the catalytic, "co-enzyme" influence of chemical substances, especially inorganic salts, concentrated in areas of injury and inflammation, on the rate of oxidation and growth of surrounding cells, was thoroughly discussed. In a more recent experimental study² of a preliminary nature, the writer emphasized the possible influence of intracellular, oxidizing enzymes, such as peroxidase and catalase, in causing and checking malignant growth. It is the purpose of this paper to discuss in more detail the different points upon which our Enzyme Theory is based.

The study of cancer may be separated into three periods: (1) The period of old theories, in which numerous hypotheses but few facts concerning etiology were advanced. (2) The period of experimental cancer research (of the last decade or so) in which a large number of important facts have been brought to light, but without the formation of any new theory of value. (3) The period of the present and near future, in which knowledge of older theories and of recent facts should be combined in an attempt to explain the mystery of this dread disease.

It may be said that those investigators who have definite convictions as to the cause of cancer are divided in their beliefs. One class of workers tells

us that cancer is probably due to a biological or biochemical action of some kind, while the other class feels certain that a parasite, or living microorganism is the cause. Our enzyme theory may be said to be a compromise between these two extremes, inasmuch as enzymes are very closely associated with the biochemistry and biophysics of the cell, while at the same time they are non-living ferments somewhat closely related to bacteria (which are nothing more than living ferments—or ferments in an organized state).

Calkins³ says: "The value of an hypothesis is measured by the number of phenomena which it accounts for." Morgan⁴ expresses like views when he says: "The value of a scientific hypothesis depends, it seems to me, first, on the possibility of testing it by direct observation, or by experiment; second, on whether it leads to advance; and, lastly, on its elimination of certain possibilities." It is the hope of the writer that his theory may fulfill some or all of the above requirements, and that the results of the preliminary,² and later, experimental work will strengthen the hypothesis. A complete bibliography will not be attempted, only those references being given which appear to have a direct bearing on the subject matter of this paper. For recent extensive bibliographies covering the field of cancer knowledge, the reader is referred to the works of Bainbridge⁵ and Woglom.⁶

To attract attention from the much studied morphological and microscopical aspects of cancer and tumors in general, there is no definition better suited than the following: "Tumors are anomalous manifestations of cell energy." It is interesting to note that this definition is found in a book on Pathological Anatomy.⁷

A further quotation from this same book⁷ may throw light on the general discussion of our theory. "It is rather a matter for surprise that ever-changing, self-regenerating living tissue does not oftener go astray in its activities than that it should only now and then do so. This latter somewhat inverted point of view may be useful in calling away the attention, in discussing the etiology of tumors, from a too close regard to extraneous factors, and directing it to the many still unexplored fields in cell physiology with which we must perhaps become familiar before we can with fair hope of success attack the serious problems of both the excitation and the prevention of tumors." With Calkins, the writer believes that "the cause of cancer—the subtlest of human diseases today—is essentially a biological problem," and that "attention must be focused upon the underlying biological phenomenon of the division energy of the individual cancer cell."

Speaking of a study of the cell, Mann⁸ says: "It is only by histological research based on a sound knowledge of chemistry and physics that we will be able to understand and to modify the events in the life-cycle, that we will be able to accelerate and to slow down nuclear and cytoplasmic activities. The importance of such research in connection with cancer and all fevers cannot be overestimated."

There is no questioning the fact that histological study of malignant growths has nearly reached its limit. The line of work for the future, in the field of tumor research, is in the proper interpretation of these microscopical changes from the standpoints of the chemistry and physics of the normal and abnormal cell.

Bland-Sutton⁹ says: "Morbid histology has been and still is of great use in classification, diag-

nosis, and prognosis of morbid growths; for a knowledge of their cause new methods are required. For these we fix our attention on the men along the sky-line — bacteriologists, experimental physiologists, physiological chemists, and physicists; the future lies with them."

Precancerous Agents.—According to our theory of cancer etiology, the *first step* towards a malignant proliferation is usually found in *cell or tissue injury* which may be brought about by any of the following agents:

A. Non-Infective. 1. *Physical:* (a) Trauma (blow or incision). (b) Heat. (c) Cold. (d) Electricity. (e) Light rays (sunlight, x-rays, radium).

2. *Chemical:* (a) Drugs. (b) Chemical poisons. (c) Toxins. (d) Abnormal metabolic products. (e) Acids and alkalies.

3. *Functional:* (a) Over-activity. (b) Disuse.

4. *Nutritional:* (a) Interference with blood supply.

5. *Referred:* (a) Injury, at one point, referred along a nerve to a distant part where it may have its effect.

B. Infective. 1. *Living Parasitic Agents:* (a) Bacteria, (b) Protozoa. (c) Infusoria. (d) Flukes. (e) Cestodes. (f) Nematodes. (g) Insects.

In general it would seem that cancer follows injuries whose agents have had their effect over rather a long period of time.

To say that a certain cancer was not preceded by an injury it is necessary to rule out all of the above named agents. But to do this is impossible, for some of them are unseen and unappreciated in their action. This relation of cell and tissue injury and trauma to tumor growth is not a new idea. Our theory attempts to explain *how* these precancerous lesions act in starting tumors. One of the most comprehensive articles of recent years on "Injury as a Causative Factor in Cancer" was written by Coley.¹⁰ This investigator concludes that in a large number of cases a definite relation between trauma or chronic irritation and malignant tumors has been proven. He believes, however, that the injury prepares a good soil for an extrinsic agent to take effect. We believe the injury prepares the way for an intrinsic agent.

The *second step* in the precancerous period is that of *inflammation*, the reaction of cells and tissues to any of the above injuries, or, as Adami would define it, "the local attempt at the repair of injury." Based upon over six thousand autopsies on mice, of which nearly four hundred were cases of unquestioned spontaneous tumors, Slye¹¹ has come to the conclusion that "cancer is a mode of growth probably allied to regenerative processes." She has also been able to find in these cases "the finest possible gradation from inflammatory nodules, through nodules becoming malignant, to the most malignant infiltrating cancer."

In the process of inflammation certain rather mysterious chemical bodies are formed at the site of the injury which exert what is known as positive chemotaxis or attraction for the leucocytes of the blood, causing these "wandering" cells to concentrate at the point of injury. The process may be inhibited by certain means, or such strong agents may be involved in the injury that a negative chemotaxis will occur and the leucocytes be repelled instead of attracted. The migration of the leucocytes to the point of injury is also aided by their ameboid movements.

In addition to these white cells there are usually found varying numbers of red cells, which arrive at these areas either by a process of diapedesis through the walls of the blood vessels or as a result of actual hemorrhage from a ruptured capillary. Red blood cells are made up of a protoplasmic stroma and hemoglobin. This latter substance consists of globin (a protein material) and a coloring matter, hemochromogen, which contains iron. The possible influence of this concentrated iron on malignant proliferation will be referred to later.

Possible Functions of Leucocytes and Red Blood Cells in Cell Proliferation After Injury.—At this point let us leave for a time the general outline of our theory of cancer etiology, and consider in more detail the association of leucocytes and red cells with injured areas and the general functions of the former. We know that with, or closely following, the arrival of the white blood cells at the seat of injury, a proliferation of the tissue cells takes place in an attempt to repair the damage. Adami¹² says the two prominent factors in the process of inflammation in general are: "Sooner or later, proliferation of the cells immediately around the injured area; attraction of the wandering cells to the area of injury."

Besides the function attributed to the leucocyte by Metchnikoff—that of scavengers and phagocytes which rush to the point of injury and ingest bacteria and other foreign bodies, it would seem that leucocytes must have some dynamic energy or force which exerts an influence on the tissue cells to cause them to proliferate more rapidly in the process of repair. In an article on "A Study of Leucocytic Extract" Floyd and Lucas tell us "it would seem that the function of the leucocyte is by no means limited to its mechanical and digestive action upon bacteria, but that the intracellular juices have an important action. Furthermore, it is probable that with the destruction of the leucocytes there occurs a liberation of enzymes and possibly of activating bodies." It has been shown by certain investigators that one of the most important oxidizing enzymes, namely, peroxidase, is found in considerable amount in the blood where it is chiefly confined to the white cells.¹³ Red blood cells in these areas of inflammation may either be taken up by the endothelial leucocytes or they may become disintegrated, thus liberating the iron containing hemoglobin in the tissues. While the white cell contains much of the oxidizing enzyme—peroxidase, the red cell contains considerable catalase—supposedly a protector against the over-activity of peroxidase. It is interesting to note that iron has been found to act as a coenzyme or accelerator of peroxidase.

What is the stimulus, the force, the source of acceleration, which causes tissue to proliferate more rapidly than normal, and at times over-abundantly, in the process of local repair or attempt at repair? Is it too much to assume that such acceleration comes from certain intracellular oxidizing enzymes of leucocytes, or possibly from the iron of disintegrated red cells in concentrated amounts, brought to and liberated in the injured area? To this subject we will refer later.

It is known that most of the leucocytes become disintegrated in time after they have reached the point of injury, especially if the agent causing the injury persists in its effect for any length of time, causing a chronic inflammation. Following an agent the injurious effect of which is short or mild,

most of the attracted white cells may find their way back to the blood stream through the lymph channels.

Waldeyer¹⁴ was the first to emphasize the association between greatly increased tissue vascularity and early malignant growths. He called attention to the great accumulation of white cells in a large number of areas which were the sites of beginning neoplasia, and suggested that "excessive nourishment and the loosening of the connective tissue thereby assist in the advance of the epithelial cells." These areas of increased vascularity, including marked leucocyte accumulation, Waldeyer looked upon as due to repeated irritation. Enlarging upon the above ideas, our opinion is that the above mentioned "excessive nourishment" is made up largely of liberated blood-cell enzymes, or of substances which other cells use in the production of enzymes, and that they act catalytically in "speeding up" the oxidations, growth, and reproduction of neighboring cells.

Relation of Enzymes to Cancer.—It is the action of these concentrated or accelerated enzymes, and coenzymes, which the writer looks upon as the most important agency in the formation of cancer, or of any other tumor. Before considering how these enzymes may be associated with neoplasia, it will be necessary to consider at some length the general nature, actions, and properties of enzymes, as they occur normally in animal and plant cells. Vernon¹⁵ says: "The progress of research renders it more and more evident that the cellular protoplasm of all living organisms is made up very largely of ferments or enzymes, and that many or most of its properties are dependent upon their activities." Otto Cohnheim¹⁶ states: "It is now the general opinion of physiologists that living organisms effect most chemical operations by means of enzymes, i.e. enzymes are the tools of the cell." If cells go astray, is it not logical to investigate the "tools" to determine whether or not they have been changed in quality or quantity?"

The General Nature, Action, and Properties of Enzymes.—Euler¹⁷ defines enzymes as follows: "The name enzymes or unorganized ferments is given to animal or vegetable substances of unknown composition and constitution which, in the organism itself, or even independently of the organ or cells in which they reside are able to accelerate chemical reactions. The term enzyme is thus included in the much more general term catalyst. By catalyst we understand a substance which, without being required by the accelerated reaction or appearing among the final products, alters the velocity with which a chemical system strives to attain its final condition." Wells¹⁸ says: "The action of enzymes is similar to that of all catalytic agents, that is, they increase the speed of reaction." For the development of our enzyme theory, it is important to emphasize again that the law has been established for catalytic reactions and states that the reaction velocity is proportional to the quantity of catalyst—supposing the concentration of the substrate to be constant. This law has also been found to apply to most enzyme reactions.

Until recently ferments were divided into two groups: the organized ferments, such as living yeast cells and bacteria, and the non-living or unorganized ferments, which are better known as enzymes. Recent work has shown that there is no real difference between the activity of living and non-living ferments. For the sake of clearness and in the discussion of our theory, however, it

should be understood that in speaking of enzymes we have reference to the unorganized, non-living ferments.

Enzymes may be divided according to their location and place of activity. Endoenzymes or intracellular enzymes are held within the body cells, and are not secreted. Their activity is generally confined to the cell. Exoenzymes, on the other hand, are eliminated from the cells in which they are formed and have their seats of action in the solutions outside the cells. Peroxidase is an example of the former, while pepsin in the gastric juice is an illustration of the latter group.

So far it has been impossible to obtain enzymes in a pure state. For this reason, the chemistry of enzymes remains shrouded in mystery. By some investigators it is thought that enzyme action is a physical rather than a chemical phenomenon. Enzyme action has been compared to magnetism. Both disappear on heating to certain temperatures or when treated with acid or alkali. We can no more isolate and define an enzyme than we can lay hold on magnetism.

A few authorities believe that enzymes are not forms of matter, but rather of energy. Enzymes are recognized chiefly by their action, just as electricity is recognized by its action. It is impossible to find or estimate the enzyme itself. We may determine the amount of a substance before and after it has been acted upon by an enzyme. When increased action has taken place we assume that an increased amount of enzyme was present. Until enzymes can be purified and better defined we cannot hope for accurate knowledge concerning their functions in, and associations with, life processes in cells and tissues, and until the chemist or physicist can give us this information we must be content to base our ideas and experiments on what we know enzymes can accomplish in an unpurified state.

According to their action enzymes may be divided into three classes:

I.—*Hydrolytic* (mostly in extracellular metabolism): (a) *Those which attack carbohydrates*—Diastase, maltase, invertase, cellulase, inulinase, seminase, pectinase, lactase, etc. (b) *Those which attack proteins*—Pepsin, trypsin, rennin, fibrin ferment, erepsin, etc. (c) *Those which attack fats*—Lipase.

II.—*Oxidizing* (mostly in intracellular metabolism): (a) *Oxidase*—Laccase, tyrosinase, aldehyde, etc. (b) *Peroxidase*. (c) *Catalase*.

III.—*Miscellaneous*: (a) Alcoholic, (b) lactic, (c) butyric, (d) acetic.

Most of the study, and all of the popular knowledge, of enzymes or ferments relates to the first and third groups—the hydrolytic and miscellaneous enzymes. Only recently have we come to know much about the oxidizing enzymes, which would seem to be the most interesting and important of all in relation to normal and abnormal cell activities and energy.

Enzymes are of a colloid structure and upon this fact most of their properties depend. They are soluble in glycerin, salt solutions, or water. High temperatures destroy most enzymes, different enzymes being destroyed by different maximum temperatures. The optimum temperature for body enzymes is body temperature. They resist low temperatures much better than high temperatures, although cold usually retards their action. Euler¹⁷ says: "The influence of rise of temperature on an enzymic reaction is twofold—(1) Acceleration of the reaction, (2) inactivation of the enzyme."

Enzymes are precipitated from their solutions by excess of alcohol. Some exist in an inactive form called zymogen. For their activity a second substance called an activator (inorganic) or a kinase (organic) is necessary. In some cases also the activity of enzymes is often facilitated or increased by substances called coenzymes. Many of these latter are of the nature of inorganic salts or of electrolytes. From the standpoint of cancer, these so-called activators, or coenzymes, and paralyzers are doubtless of great importance. Some of these are of unknown composition, while others have a definite chemical structure. Among organic activators, salts of the bile acids may be mentioned. Acids and bases act specifically as activators of some enzymes and paralyzers of others. Catalase action is greatly retarded by acids. The uric acid diathesis is very frequently associated with cancerous growths and this may be due to the paralyzing action of such acids on the protecting enzymes or antienzymes associated with cell oxidations. The marked activating effects of salts of calcium, sodium, and magnesium on enzyme action has been noted. The activating effect of salts of the bile acids as well as that of calcium is interesting in view of the association between gallstones and gallbladder cancer.

Since the chemical structure of enzymes has not been established, all we may say is that they are colloidal, organic substances, derived from or closely related to proteins. One of their chief characteristics is that they are taken up, or adsorbed, by carbon, clay, infusorial earth, and other finely divided colloid substances. In many instances the attraction seems to be selective in nature. Most enzymes will pass through porcelain filters, some going through more readily than others. Considerable of the enzyme, however, does not always filter because it is adsorbed by the filter itself. After the filter is thoroughly saturated with the enzyme more of the latter will pass through. Euler¹¹ says: "The permeability of the Chamberland filter for enzymes depends on the concentration of the hydrogen ions in the solution. If the solution is neutral toward phenolphthalein no adsorption takes place, the filter being permeable; but if the liquid is neutral to methyl orange, the filter is impermeable." The difference in these physical conditions of the filter and of the chemical reactions of the emulsions may largely account for the variable results obtained in the attempts at the transmission of tumors by so-called "filterable agents."

Enzymes differ in their degree of susceptibility to antiseptics. Some antiseptics will destroy bacteria and cell protoplasm, but will have little effect on enzymes. Formaldehyde is very powerful in its action against enzymes, while toluol has little or no effect on enzymes. The latter is often used to keep enzyme solutions free from bacterial growth, and even to differentiate between enzymes and bacteria.

Enzymes may be properly called ultramicroscopic bodies. Because of their colloidal nature, they may be seen as very fine particles through the ultramicroscope. At times these particles may even shown Brownian movement. Frequently a large number of these small particles may coalesce and form a large mass which is much easier to see.

The "agent" (separable from the tumor) used by certain observers to cause secondary malignant proliferation is similar to an enzyme in that it may be dried, exposed to extreme cold, preserved in

glycerin (which kills most of the ordinary non-spore bearing organisms), and even passed through porcelain filters without losing its power. Heat destroys enzymes and also readily inactivates tumor cells.

Euler¹² states that "the biological action of light is of two kinds—one requiring the presence of oxygen and accelerated by fluorescent substances, and the other produced only by ultraviolet rays without any part being played by oxygen or fluorescent substances. Light exerts actions of two kinds on enzymes: (1) A *destroying action*, corresponding with denaturation by heat. (2) An *activating effect*, due to conversion of the 'zymogen' into the active enzyme." Many of these facts are interesting not only from the standpoint of the study of enzymes, but also from that of the study of cancer. Richards¹³ has found that weak radiations accelerate the action of enzymes, while strong radiations inhibit. Using pepsin and diastase he came to the conclusion that "a short radiation with x-rays has the effect of accelerating the enzymotic activity, while longer radiation inhibits it. Between these two strengths lies a point at which the radiation is non-effective." Schmidt¹⁴ treated different beans with varying doses of x-rays and then noticed the effect upon their subsequent growth. Large doses of x-rays inhibited the growth of the beans, while small doses greatly accelerated the growth, even above the normal rate found in untreated beans. It is our belief that these x-ray effects were upon the enzymes of the bean which have to do with their energy and growth rate.

Euler¹⁵ writes that "in general, it may be stated that the healing action found by experience to be exerted by radium emanation depends on activation of enzymes. The promotion of plant growth by the emanation is also to be attributed to enzyme activation." These results, as previously mentioned, are dependent upon weak radiations—the opposite effect being associated with strong radiations. X-rays and radium thus have a *double* effect upon enzymes. Such rays also have a *double*, and apparently *opposite* effect upon cells of the body. For this reason Lazarus Barlow¹⁶ goes so far as to uphold the idea that cancer may be both caused and cured by radiations. While many workers have demonstrated the retrogression and even the cure of animal and human cancer by the use of radium, Rovsing¹⁷ and others have come to the conclusion, after considerable study, that radium promotes cancer growth instead of checking it. *Both of these findings may be correct.* Some workers use weak and unconcentrated radiations and get stimulation of tissue and cells due to acceleration of enzymes. This class sees danger in the use of rays. Others, seeing helpful effects, use strong, concentrated rays and thus cause destruction of cell life due to the inhibiting effect upon enzymes. A third class of workers use medium radiations and get no effect, from which they conclude that radiations are of no value. *All of which argues for large experience if one wishes good results in the treatment of cancer by x-rays or radium.* Furthermore, some fluorescent substances act as sensitizers in generally accelerating enzyme activity. Does this give a hint as to the reason for such a high percentage of cancer of the urinary tract in workers in aniline dyes, or for the marked epithelial proliferation caused experimentally by injection of Scharlach R or Sudan III?

Aniline in certain concentrations has been demonstrated to have a powerful paralyzing, or inhibit-

ing, effect upon the action of catalase. Thus it may be that the increased percentage of cancer in those whose occupation brings them into close contact with aniline, and other related hydrocarbons and their derivatives, such as pitch, tar, paraffin, and petroleum, is due not so much to definite stimulation from these chemical bodies, but rather to an inhibition of catalase action and, hence, a paralysis (either local or general) of those protecting forces which guard the body cells and tissues against riotous and injurious cell oxidations. It is certainly significant that most of the substances which have been demonstrated to have a rather close association with cancer etiology are quite intimately related in the group of hydrocarbons and their derivatives, and that they have definite effects upon cell enzymes.

Enzymes may cause the production, in the living body, of antienzymes, just as toxins may stimulate the production of antitoxins. These may be produced by active immunization or in some instances may be found naturally in normal serum. Antienzymes do not destroy enzymes, but merely inhibit their action. Many, or most, of the protective substances in the body are of the nature of antienzymes. Regarding antienzymes, Hammarsten²³ says: "They are perhaps of the greatest importance in life in retarding or regulating the action of the intracellular enzymes."

Relation of Enzymes to Tissue Respiration (or Energesis) and Vital Activities.—Vernon¹⁸ says: "The processes of oxidation which are continuously taking place in all living tissues are even more important than those of hydrolysis, in that they are chiefly responsible for the production of heat and other forms of energy. Though our knowledge of the subject is at present very fragmentary, it seems probable that these oxidations are brought about by intracellular oxidizing enzymes."

The true oxidases are of wide distribution, but not present in all tissues. Kastle¹⁹ gives the following "classification of the oxidases and other oxygen carriers concerned in biological oxidations":

"(1) Laccase, ferments oxidizing guaiacum, guaiacol, hydroquinone, phenolphthalein, tannin, etc.

"(2) Trypsinase, ferments acting on tyrosin and related substances.

"(3) Aldehydase, ferments oxidizing aromatic aldehydes and related compounds.

"(4) Indophenol oxidase, ferments oxidizing a mixture of α -naphthol and paraphenylene diamine to indophenol and other substances.

"(5) The purin oxidases.

"(6) Glycolytic, ferments causing the disappearance of sugar from animal tissues."

As stated above, these oxidases are found in many forms of animal and plant life. However, they are not so directly associated with the oxidation process in plants and animals as are:

"(1) Peroxidases; oxidizing oxidase reagents only in the presence of a peroxide, such as hydrogen peroxide. . . . According to Moore and Whitley the peroxidase is the only type of enzyme concerned in oxidizing processes occurring in living cells and tissues.

"(2) Catalases. These ferments actively decompose hydrogen peroxide, but are incapable of effecting the oxidation of oxidase reagents by means of the peroxide."

It may be said that practically all living animal and plant cells contain peroxidase and catalase. In

the blood of animals the enzyme peroxidase is chiefly confined to the white cells. Catalase is found most abundantly in the fatty tissues of the body, also in the liver, spleen, and blood (especially in the red cells of the latter).

Loew²⁴ believes that the function of catalase is to destroy the hydrogen peroxide as it is formed in the cells and tissues as a result of the cell respiratory process. Others, also, have arrived at the conclusion that catalase protects the tissues against injurious oxidations. Abderhalden²⁵ in speaking of catalase, says: "Thus the cells evidently possess a means of restricting and regulating the activity of the oxidation processes taking place within them."

According to Jolles and Oppenheim²⁶ the "catalase value" for normal blood is 23. In carcinomatous conditions they found a greater decrease than in any other disease studied—the catalase values of the blood falling to 1.3-2.1. A possible interpretation of these findings is that the injurious oxidations taking place in the cancer have put a great demand upon the protecting enzyme catalase, thus markedly reducing the supply in the blood. It was with these, and other, facts in mind that experiments²⁷ were undertaken to determine the influence of concentrated catalase upon transplanted rat carcinoma. The results seem to indicate that the diminished store of catalase available for combating the tumor may be so replenished that its protecting influence is greatly enhanced, and the injurious oxidations and growth of the tumor held in check, or even made to disappear.

Buxton²⁸ and also MacFadyen and Harden²⁹ have demonstrated the almost constant presence in tumors of such oxidizing enzymes as peroxidase and catalase. Their mere presence is of no great significance (for they are found also in all normal cells), unless it be to further emphasize the similarity in constitution of normal cells and cancer cells. The important features to study are the exact amounts and concentration of these enzymes in normal cells and tumor cells, and the difference in catalytic power and activity of the enzymes in such cells. The difficulty in measuring exact amounts of enzymes has already been mentioned.

Starling³⁰ states that "so wide is their (enzymes) dominion in cell chemistry that many physiologists have thought that the whole of life is really a continual series of ferment actions." Abderhalden³¹ says: "The ferments are unquestionably closely related to the life-processes of the cells." Howell³² tells us that "in life the endoenzymes play their part within the bounds of the cell in which they are contained, and probably constitute the chief means through which are effected the metabolic processes that characterize living matter." Wells³³ is satisfied with saying that "the factors which incite cells to proliferate, as well as those that cause the cessation of proliferation after it has once started, are too entirely unknown to permit of speculation as to their exact nature." He agrees with Ziegler, however, "that they are identical with the stimuli which excite or increase functional and nutritive activity, and that these are in many instances of a chemical nature." He further admits "at the very least, however, we may look upon the intracellular enzymes as the most important known agents of cell metabolism, and consequently of all life manifestations; and the changes they undergo or produce in pathological conditions must be fully as fundamentally important as is their relation to physiological processes."

In the light of recent work on enzymes is it not possible to say that the activity of certain intracellular enzymes (oxidizing enzymes) is probably the stimulus to, or speed regulator of, intracellular oxidations and tissue respiration or energesis? If we admit that cell and tissue activity and growth depend on cell and tissue oxidations or respirations, then it is possible to see how the action of these intracellular oxidizing enzymes is the regulator, if not the source, of growth and cell-division. Jacques Loeb³¹ assumes that there is a direct relation between oxidations and cell-division when he says: "If we suppress the oxidations, we suppress also the processes leading to cell-division." This association of enzyme-like substances with vital oxidation was first demonstrated by the chemist Schoenbein of Basel. Regarding this association we again quote from Howell.³⁰ "The oxidations of the body those reactions that give rise to much heat . . . take place under the influence of the living matter, or by the aid of substances (enzymes) formed by living matter." "The point of view actually adopted by most workers is that the living matter effects its wonderful changes in the food matter with the aid of intracellular ferments or enzymes." "The supposition has naturally been made that probably the oxidations of the body are effected also by enzymes which in some way activate the oxygen. Enzymes of this character have been found; they are designated in general as oxidases and peroxidases. Whereas formerly the general belief among physiologists was that physiological or vital oxidations were effected as part of the metabolism of the living substance, the tendency at present is to assume that these oxidations are not effected directly by changes in the living substance, but indirectly, in that the latter forms these oxidases or peroxidases, which have the property of liberating oxygen in an active form. The oxidations effected by this means are the principal source of the development of heat in the body. Many physiologists believe that a portion of this heat is used in the work of the body, the muscular contractions, for example, *or the growth of new living tissue*. That is to say, they regard the body as a sort of thermodynamical engine in which the energy of the food is obtained first as heat, and the heat is then utilized in part for the other energy needs of the body."

Speaking of specific enzymes, Kastle³² says: "It would seem, therefore, that it is not the oxidase, but rather the peroxidase which is the most important agent in plant and animal oxidations . . ."

Jacques Loeb³¹ makes the statement that "the specific substances which accelerate the oxidations at body temperature sufficiently to allow the maintenance of life are the so-called ferments of oxidation. The work of Lavoisier and Laplace not only marks the beginning of scientific biology; it also touches the core of the problem of life; *for it seems that oxidations form a part, if not the basis, of all life phenomena in higher organisms*." Spitzer³³ demonstrated, at least to his own satisfaction, that the most important oxidizing enzymes of the cell are located in the nucleus. Based on these findings, Jacques Loeb³³ "pointed out that the cell nucleus must be regarded as the essential respiratory or oxidizing organ of the cell."

Speaking further on the activation of the egg, Loeb says: "The spermatozoon causes the development by accelerating the oxidations in the egg." This he believes is brought about by two factors: 1. Cytolysis, by some chemical lysis, of the thin

cortical layer of the egg—which initiates development. 2. An unknown substance containing, or acting on, oxygen which modifies the process of oxidation, and which is necessary for complete development.

Wells³⁴ says: "Although oxidation of organic compounds is the chief source of energy in the animal body, yet the way in which it is accomplished is very little understood. We only know that it is brought about within the cells. . . . There can be little question that this oxidation is accomplished through catalytic agents acting within the cells. . . ."

That oxygen is essential for the growth of cells and tissues is evident from the following statement of Leo Loeb:³⁴ "Our experiments show that complete lack of oxygen not only prevents the growth of tissues, but causes their complete death; anaerobic life seems to be impossible for mammalian tissue; this applies to normal tissues as well as to tumors. In experiments on the other hand in which we increase the oxygen in the atmosphere surrounding the piece of tissue, we found both the life of the tissues and the growth phenomena increased."

Jacques Loeb³³ also emphasizes that "there are, however, other vital processes which are more general than those of locomotion and heat production, which also require oxygen, *i.e.* cell division and growth."

Marshall and Rowntree³⁵ tell us that "the possibility of the increased rate of growth in plants (germinating oats, for instance) being due in part to enzymatic activation has been suggested." From Oosthuizen and Shedd³⁶ we quote: "A great deal of work has been done in the last few years on the changes taking place in the germination and growth of seeds. It is now generally recognized that these changes depend primarily upon what are commonly called ferments or enzymes." These authors also speak of certain work by Waugh on the effect of enzymes on seeds in which he arrives at the following conclusions: "1. In some cases the percentage of germination in seeds is greatly increased by soaking for several hours in a solution containing some active enzyme or enzymes. 2. The vigor of the young plantlets is often enhanced at the same time. 3. Within limits these beneficial effects increase with the strength of the enzyme solution. Corn has been found to show increased germination, and also increased vitality in growth under the influence of an enzyme. Others have obtained the same results with seeds of barley, oats, peas, etc.—namely, increased germination and vigor of growth in the presence of certain enzymes."

Falta and Schwarz³⁷ have attributed the promotion of plant-growth by radium emanation to enzyme activation.

Thus, enough evidence may be found to show that intracellular enzyme action, chiefly oxidizing in character, has an important function in the metabolism, growth, and reproduction of normal cells, both of the animal and plant kingdoms.

Minot³⁸ believed that "by nourishing itself, protoplasm grows, and as a consequence thereof follows the multiplication or proliferation of cells." More rapid multiplication and proliferation are probably dependent upon more rapid growth.

Difference in Speeds of Normal and Cancer Cell Proliferation.—Cell proliferation in tumors is different from cell proliferation under normal conditions primarily in degree. In the former, cell reactions have been greatly accelerated and the growth rate is much faster than in the latter, and

is dependent upon increased concentration and activity of these same oxidizing enzymes or catalyzers, with a lack of their proper inhibition. Howard and Shultz²⁹ have shown that the other characteristics of a tumor cell, such as increased division rate, lack of differentiation, etc., are dependent upon increased growth rate. Mallory¹⁰ also assumes that the embryonic type of cell is due to rapid growth when he says: "If a tumor grows rapidly its cells do not have time to differentiate to any extent; they remain of an embryonic type. . . ."

The important thing to explain, then, is the agent or force which initiates the change from normal cell growth rate to tumor cell growth rate, and which results in a permanent acceleration of energy in a local cell or mass of cells.

Howard and Schultz²⁹ believe that "Dynamic energy, produced by cellular metabolism, manifests itself in cellular growth and function. . . . In the malignant tumor cell the maximum limit of energy production for the normal cell is overstepped and the energy produced is abnormally distributed to the advantage of growth rather than of function." Carrel³ says: "The dynamic condition of a tissue is manifested by the rate of its growth." From this may we not conclude that the excessive growth rate of tumors is a manifestation of increased dynamic force and energy in the individual cells involved? If so, does not the cancer problem resolve itself into a question of increased cellular dynamic energy? *Is it not proper to first consider how the normal sources of cell energy might be associated with this change, instead of looking for some extrinsic agent?* "It must be remembered that in cancer we have cell proliferation going on at a rate which is unknown in any other condition in grown up animals, and many of the appearances, both as regards the irregularity of mitosis and as regards cell inclusions, may be the result of this great rapidity of proliferation," says White.⁴

What is the cause of this "overstepping" of normal cell energy, or of this acceleration in the biochemical activities leading to accelerated energy production and growth? In the answer to this question we believe may be found the "formative stimulus" of tumors.

The "Formative Stimulus."—The writer believes the cause of this acceleration to be the catalytic action of local, concentrated oxidizing enzymes (particularly peroxidase), or an increase in their co-enzymes (accelerators), in one or more previously normal cells; these cells take on a new, independent energy production and growth rate as a result. *The transmission of this newly acquired concentration, or accelerated action, of endoenzymes from parent cell to daughter cells assures the progeny a permanent and independent increase in oxidations, energy production, growth rate, and division rate.* This concentration may be brought about through the process of injury and inflammation, as outlined above, in which the leucocytes are attracted to an area where their enzymes are liberated in an abnormal amount. Injury (mechanical, chemical, or parasitic) may also be of importance in first causing a cytolysis of the lipoids of the normal, but potential cancer cell (as has been shown by J. Loeb to be the case in the natural fertilization of the egg, or in so-called "artificial parthenogenesis"). We must admit, also, that there are other forces such as light and heat rays which may directly stimulate enzyme activity, or which may attract and cause the localization and concentration of enzymes themselves. In fact, the writer believes

that cancer of the lip in clay pipe smokers, cancer of the scrotum in chimney-sweeps, and cancer of the skin in wearers of the hot charcoal Kangri basket, are due in large part to the attraction, concentration, and acceleration of enzymes by the localized adsorbing clay or carbon, in addition to a rise in temperature, followed by increased oxidations permanently established in such local areas.

Buyo cheek cancer, prevalent in the Philippine Islands, seems to be caused in a very definite manner by the irritation of the buyo which is chewed by male and female natives. Buyo consists of a mixture of buyo leaves, betel-nut, slaked lime, and tobacco. Davis³⁰ believes that the active agent in the causation of the buyo cheek cancer is the lime. From a study of enzymes it is found that lime may act as an adsorbent and concentrator of enzymes, while it is also learned that calcium is an important activator of enzyme action (a co-enzyme). In connection with cheek cancer it may act by catalytically "speeding up" the enzyme action and oxidations of local epithelial cells.

Richards³¹ says: "The speed of the chemical changes in the human body is a matter of capital importance to man. Indeed, it may be said that the difference between health and disease, between life and death, is primarily a question of the relative speeds of the various reactions concerned in the act of living. There is fortunately a wide margin of safety, but nevertheless, if anyone of the more essential chemical changes takes place too fast or too slowly, illness is certain consequence. All chemical reactions are dependent for their speed upon a few very definite circumstances, to wit: the special affinities of the substances concerned, the concentration of the reaction substances, the temperature of the mixtures, and the presence or absence of certain other substances (called catalyzers or catalysts) which do not themselves take part, but which stimulate the reacting substances to enter into combination. Each of these factors in the result is of great importance to the biologist. *The effect of concentration is especially interesting; it influences all the various kinds of reactions, whether between a liquid and a solid, between a liquid and a gas, or between several substances dissolved in a single liquid.* Whenever to a nearly balanced mixture more of any reacting substance is added, it tends to push faster and farther all the changes in which it takes part, so that some of the added substance is used up. For example, if more water is added, all the reactions which tend to use or absorb water are accelerated, and so forth. This is a very general law which is susceptible to mathematical expression in each separate case."

The above statements would seem to apply to individual cells, as much as to tissue, organs, or the body in general. *According to our enzyme theory, the difference between a normal cell and a cancer cell is essentially a difference in the speeds of their biochemical reactions, depending upon a difference in their intracellular enzyme and co-enzyme concentration and activity, more especially of their oxidizing enzymes.* In the words of Bell³² of England it would seem that "the cancer entity is . . . in its original state, a normal cell, which has from a combination of circumstances become altered in character, not towards degeneracy, as I construe the term, but to increased activity."

Inasmuch as it has been shown by certain investigators that much of the normal exo-enzyme activity in the body is regulated and kept in check by the so-called anti-enzymes, it would seem that

the normal energy production, growth, and division of cells, which are so dependent upon the intracellular oxidizing enzymes, may also be regulated by anti-enzymes.

Definition of Cancer.—According to our theory, cancer is the result of a combination of a local "formative stimulus," in the nature of concentrated oxidizing enzymes or accelerating co-enzymes, in one or more previously normal epithelial cells, with a general or local decrease (either hereditary or acquired) of the enzymes and anti-enzymes which control cell oxidation and proliferation.

Well-Known Theories Examined in the Light of an Enzyme Theory.—In regard to the cause of cancer, Adami¹ says: "All recognize a change in cell properties, but none lay down what is the underlying influence or stimulus which brings this change about." He states further that "We recognize an inherent and permanent alteration in the properties of the cells that constitute, or are to constitute, the neoplasm. It is not something from without that determines the continued growth, not an external stimulus, nor again a diminished external resistance. An external stimulus, it may be, starts the cells on the path which leads eventually to their assuming neoplastic properties; diminished external resistance may well favor active neoplastic growth. . . . The more we study the life history of the different orders of tumors, the more we investigate the circumstances associated with the development of different examples of one particular order of tumor (such as the carcinomas), the more it is impressed upon us that there is no one specific causative agent, that a multiplicity of agents induces a particular grade of cell reaction; all these causes may lead to a modification that is not transient but permanent and conveyed to subsequent cell generations." Adami and others believe that loss of cell function is closely associated with increased vegetative activity or power of growth. This idea is of interest from our standpoint and may be explained as follows: Increased oxidizing enzyme action (from all causes) leads to increased cell oxidations resulting in rapidity of growth and of reproduction, but, on the other hand, causing an inhibition of cell function. In a recent paper by Loevenhart² on Vital Oxidation, experiments are described which demonstrate the relation between vital oxidation and functional activity. It is shown that a decrease in the rate of oxidation in cells of the medulla resulted in increased functional activity, and vice versa. It is, therefore, concluded that functional activity varies inversely with the rate of these cell oxidations. Pasteur³ discovered that with a lack of oxygen, yeast cells grow very slowly or not at all, while their fermentative function is more energetic.

Concerning the cause of cancer, Mallory⁴ says: "Evidently something starts the cells, which produce a tumor, to proliferate just as a spermatozoon influences an ovum, or as recent experimental work has shown conclusively various chemical reagents may do."

According to the popular theory of Cohnheim a neoplasm originates in displaced embryonic cells or "rests." He did not explain satisfactorily, however, the cause for the sudden, rapid proliferation of these cells. His theory may cover the origin of some tumors arising from embryonic cells, but the immediate cause we believe is a combination of the inherent energy of embryonic cells, and a local or general decrease from one cause or another of the protecting enzymes and anti-enzymes.

Ribbert's theory lays more emphasis on a decrease in the external resistance and forces which oppose the growth of cells, but he assumes this resistance to be rather mechanical or physical in nature and a question largely of tissue tension. Our theory recognizes as essential a decrease in controlling forces, but we believe these forces are biochemical in nature and due to the action of enzymes and anti-enzymes.

The popular ideas which give injury, chronic irritation, or inflammation, a chief rôle in the production of tumors are substantiated in our theory. We simply go a little farther and endeavor to explain how these precancerous agents act in bringing about a concentration of enzymes, a permanent acceleration in cell oxidations, energy, and proliferation in the local areas which they affect; also, how these cells with new capacities for proliferation run riot when the controlling anti-bodies or anti-enzymes are insufficient to longer hold them in check. The numerous "parasitic" theories also appear more tenable when we assume that no one parasitic or microbic agent is the immediate cause of cancer, but that any or all infective microorganisms may be included in the large group or "precancerous" agents which lead to injury, inflammation, and finally to an upset in the normal enzyme properties, equilibrium, and activities of cells. So great a pathologist as Ziegler⁵ says: "The natural history and clinical behavior of cancer are not such as to make it probable that it is of parasitic nature." Speaking of the cause of unlimited atypical proliferation of epithelium, he says further: "Whether this cause is to be found in a bioplastic stimulus comparable to that of fertilization, or in chemical influences stimulating the cells to increased proliferation, or in the removal of the influences that inhibit and regulate proliferation, cannot be stated at the present time." It is evident that he is much more in favor of the latter possibilities than of those of a specific parasitic causation.

White⁶ says: "Cell proliferation in tumors is similar to cell proliferation under normal conditions. The assumption of a parasite to explain the causation of tumors is unnecessary." Tyzzer,⁷ of the Harvard Cancer Commission, believes that "the accumulation of evidence . . . tends to show the non-infectious nature of tumors in general."

Speaking in favor of the action of an intracellular microorganism as the cause of cancer, Calkins⁸ says: "The cancer cells must carry with them the sources of their stimuli." In answer to this it may be said that so also must normal cells carry with them the sources of their stimuli, and there is no idea that such stimuli come from intracellular parasites. We believe the stimuli in both cases come from intracellular enzyme reactions, of different degrees and intensities.

Virchow⁹ emphasized the analogy between the fertilization of the ovum and the growth of the cancer cell. In the former, segmentation, growth, and proliferation do not begin until the spermatozoon has entered the ovum. In cancer, he suggested the possibility of a fertilizing agent acting on normal cells to bring about malignant growth. Klebs¹⁰ observed that leucocytes which had been found in or between cancer cells might "fertilize" normal epithelial cells and thus result in malignant proliferation. The ideas of Virchow are substantiated by Jacques Loeb¹¹ who says: "The analogy between the causation of the development of the egg by a spermatozoon and the causation of a pathological

growth seems correct." We know that the first process is one of an accelerated rate of oxidation. According to the analogies of Virchow and Loeb, and to our enzyme theory, a new growth is also due to a permanent local acceleration in the rate of intracellular oxidations brought about chiefly through the catalytic action of concentrated or accelerated intracellular oxidizing enzymes, following injuries and other influences.

Beard⁵³ believes that "at the basis, cancer is nothing more than the production abnormally of an asexual generation within a sexual generation." He has described it also as "an irresponsible trophoblast." Because the suppression of the trophoblast in the developing embryo occurs at the same time that the pancreas begins to functionate, he has decided that the former is a result of the latter. Based upon this, he has recommended the use of pancreatic ferments in the treatment of malignancy. His theory does not help us any more than does Cohnheim's. He does not explain why, even though the pancreas retains its normal activity, these "asexual cells" lie dormant for many years and then suddenly begin to proliferate in a malignant manner.

Without going into details concerning the many other minor theories of the cause of tumors, suffice it to say that many of them are explainable if analyzed in the light of an enzyme theory.

Experimental Transplantation, and an Enzyme Theory.—A careful study of the facts brought out in relation to the experimental transplantation of tumors does not reveal anything which rules out the possibility of concentrated intracellular enzymes acting as the etiological factor in the continued growth from one generation to another. In this work it is admitted by most authorities that it is not a question of infection, but one of transplantation, and that the tumors develop not from the cells of the host but from the original cells injected. Of course, the tumor producing agency must of necessity be transferred at the same time. This agent does not need to be a living microorganism, and is probably the normal intracellular oxidizing enzymes in more concentrated form. The fact that tumors may be transplanted successfully only in very closely related animals also speaks in favor of a very fine adjustment in biochemical activities, and against any specific parasite. The retention of life and activity of both tumor cells and enzymes exposed to extreme cold has been demonstrated. Likewise both are very susceptible to heat.

Haaland⁵⁴ demonstrated that radium destroyed the growth power and life of the cancer cell without in any way altering its anatomical structure. It has been shown that radium has a very definite effect on enzymes, and it may very well be that this effect in Haaland's work was on the intracellular enzymes of the cancer cells.

Immunity and Enzymes.—That natural and acquired immunity to experimental inoculation of cancer may be demonstrated, is admitted by most authorities. Active resistance may be brought about by inoculation with living tumor cells and even by normal cells and tissues such as blood, spleen, liver, and embryo. Bashford⁵⁵ showed that the injection of mouse blood produced a resistance against mouse tumors. Borrel⁵⁶ found that the injection of liver or spleen also led to a resistance. The injections of mouse embryo suspensions led to a definite resistance against the development of tumors, according to Schoene.⁵⁷ Jobling⁵⁸ confirmed Bashford's work and demonstrated "the effects of

the injection of washed corpuscles of the rat into the peritoneal cavity on the development of grafts of this rat tumor . . . to be considerable."

To the writer these seem very significant facts. They certainly speak very much against immunity being established by the influence of living parasitic microorganisms, and point to an immunity or resistance stimulated by cells, or cell contents, such as enzymes.

The theories concerning the nature of immunity to inoculated tumors are many, three of which are worthy of mention: (1) *Ehrlich's theory of Athrepsia*—According to this theory the specific food substance supposed to be necessary for cancer cells is bound by the immunizing cells and hence is not available for the cancer and the latter disappears for want of proper food. (2) *Bashford's Theory*—The immunity is described as being due to a failure of the organism of the host to supply a specific connective tissue stroma reaction to support and nourish the cancer. (3) *Borrel-Levin Theory*—Immunity in experimental cancer is analogous to bacterial immunity and is caused by certain cytolytic bodies circulating in the blood. These bodies are supposed to be "ferments" of unknown character and action.

According to our enzyme theory, immunity is due, in these cases of experimental cancer at least, to anti-enzymes which are naturally present in normal amounts, or which may be artificially stimulated and increased (either actively or passively) by the intracellular oxidizing enzymes of normal cells, or of tumor cells, which have been injected for the purpose of immunization. Such "protecting" enzymes as catalase are also undoubtedly involved in the resistance of the body against tumor formation, and other forms of injurious oxidations.

"Filterable Agents" and Enzymes.—The work of Rous⁵⁹ in transmitting different forms of fowl "sarcoma" from one chicken to another by agents which pass through Berkefeld filters is doubtless the most important demonstration in the field of cancer research during the past few years. It certainly points to some specific etiological agent which is able to pass through these fine filters. The first thought is that the agent is an ultra-microscopic and filterable parasite or microorganism, but as has been suggested above, all other evidence is very much against the idea that true malignant tumors are caused by specific living microorganisms. On the other hand, cellular enzymes are ultra-microscopic in character, and are filterable under certain conditions. It is quite possible that the above described "filterable agents," separated from the tumor cells, were concentrated intracellular oxidizing enzymes specific for certain cells, whose catalytic action affected similar cells or "substrates" in the new host, resulting in neoplastic change.

Treatment in the Light of an Enzyme Theory.—It may truthfully be said that the non-operative agents which have been used in the treatment of human cancer, and of transplanted cancer in animals, are agents which have a direct and undoubted action against oxidizing enzymes. We may mention x-rays, radium, electricity, and heat in the field of physiotherapy. In reference to the last agent, Percy⁶⁰ says: "It is logical that there may be hope for the eradication of cancerous growths by attacking them through their vulnerability to heat. Heat and not cauterization is the object to be attained."

Heavy metals in colloid form have been used with considerable success in the treatment of human and experimental cancer from a biochemical stand-

point. These colloidal metals are often described as "inorganic ferments" or "inorganic catalysts." Both the oxidizing enzyme, catalase, and colloidal metals decompose hydrogen peroxide. Their chemical actions are the same, resulting in the formation of water and inert molecular oxygen. In experimenting with the enzyme, catalase, our results² in causing the disappearance of transplanted rat carcinoma are very similar to those obtained by other workers who used colloidal metals. A conclusion which may be reached is that both catalase and colloid metals, in decomposing hydrogen peroxide, check the injurious oxidations going on in tumors; and by checking these oxidations—destroying the life and vitality of the tumors, which are dependent upon these greatly increased oxidations for their very existence.

Immune serum, embryo, and other normal tissues, tumor emulsion, ascitic fluid from cancer cases, and bacterial toxins, have all been used with variable success in the biotherapy of cancer. It is quite probable that in such cases the influence has been due to protecting enzymes or anti-enzymes either actively or passively stimulated, or, in the case of induced infections or toxemia, to the effect of rise in body temperature on enzyme activity.

Organotherapy has been used to some extent in the non-operative treatment of tumors. Thus, the use of thyroid extract has been followed by beneficial results in some cases of cancer. This is interesting from our standpoint, when it is learned that in hyperthyroidism, the catalase activity of the blood is increased, while it is decreased in hypothyroidism, only to be again increased by the feeding of thyroid. Evidently the ductless glands are directly related to the enzyme activities of the body.

Cause of Non-malignant Tumors from an Enzyme Theory Standpoint.—As has been stated before, the theory which explains neoplasia must explain not only the cause of cancer but also the causes of all other tumors, benign and malignant.

According to our theory, the causation of the various tumors is explainable by assuming the action of oxidizing enzymes in concentrated form or accelerated activity to take place on "substrates" in different types of body cells.

We may obtain light on this point by studying the proliferation and regeneration capacities of body cells in comparison with their tendency to form tumors.

The body tissues may be divided into four groups: (1) Epithelial (and glandular); (2) supporting and interstitial (including connective tissue, embryonic and adult, cartilage and bone); (3) muscle; (4) nerve.

The most prolific or rapidly growing tissues of the body, those that are easily and completely regenerated, are epithelium, blood cells, and young connective tissues. They start with more vital force and power and they are undoubtedly richer in intracellular oxidizing enzymes than other cells. Is it to be wondered at that when their oxidations are still further accelerated by catalysis, their increased powers of growth, and energy, and possibly ameboid movement, will result in anything but lawlessness, infiltration, and malignancy? On the other hand, the cells and tissues, such as muscle and nerve, which show slow, or absent, proliferative and regenerative powers, are the ones which give rise to slow growing, benign tumors. Catalytic acceleration in a localized area of their naturally slow oxidations, and reproductions, will result in evident growth increase, but as a rule this increase will be

slow and deliberate enough to allow the physical and chemical anti-forces of their own cells and neighboring tissues to hold them in check.

The Predisposing Causes of Cancer in Relation to an Enzyme Theory.—The predisposing causes of cancer may be divided into: (a) Hereditary influences. (b) Environmental influences, especially as regards chronic irritation and inflammation, either accidental in nature or associated with habits, occupations, etc.

Although hereditary influences are included under predisposing causes, it must be admitted that no definite proof has been found that heredity plays any important part in human cancer. On the other hand evidence³ is available which points to the probability that cancer in mice is "hereditary in the strict sense." Slye says: "It follows the laws of heredity with an inevitableness which makes it a character that can be manipulated. It can be bred into and out of strains at will. It can be put into a strain where it has never existed before and it can be drawn out in extracted lines which can produce nothing else, and which in turn will carry cancer into any line with which they are hybridized; or it can be bred out of a line one side of which originally carried 100 per cent. cancer. Cancer is not transmitted as such, but rather as a tendency to occur from a given provocation, probably in the form of over-irritation." She says further that "the results obtained from this series of experiments show beyond a doubt that the tendency to produce neoplasms under the right provocation is transmitted from generation to generation with the inevitableness of the transmission of albinism."

Our theory of cancer etiology is not weakened by the fact that cancer may be closely associated with hereditary influences. The influence of heredity upon body color, such as the color of hair and eyes, and the pigmentation of skin (including the phenomenon of albinism) is well recognized. Tower,⁴ in a discussion of the color of organisms, says: "In modifications of color we are dealing with superficial chemical processes in the organism—the development of a chromogen and the oxidation of that chromogen by one or more oxidizing enzymes to a state of stability where simpler compounds are produced which are productive of color. In no experiments in the modification of color, especially in colors such as the melanins, etc., has any modification been produced which is not an accentuation or diminution of the oxidative capacity of the organism."

If such enzyme actions and oxidations which have to do with color are hereditary in character, may not cell enzyme activities and oxidations, which lead to cancer, also be dependent, in some instances at least, upon the hereditary influences of "determiners," lack of "determiners," or of "inhibitors"?

In connection with the dependence of animal color on oxidizing enzyme action, and our ideas concerning the influence of oxidizing enzymes, antienzymes, and coenzymes in causing cancer, the work of Lathrop and Loeb on the "Origin of Tumors in Mice"⁵ is most interesting. These workers have found that "It is possible to split a strain of mice into certain substrains in which the tumor incidence is in some way linked to the color of the mice. . . . Therefore, certain combinations of factors which determine certain colors of mice determine at the same time the tumor incidence of these strains or substrains."

Concerning environmental influences associated with occupations, it may be said that the very

marked occurrence of cancer in those who work constantly with tar, petroleum, paraffin, aniline, or who wear the hot charcoal Kangri basket, or whose life and work bring them in contact with a large amount of soot, is admitted by all authorities. Even coal is described by some authorities as being an etiological agent in cancer. The writer believes it a very significant fact that all of these agents are closely related hydrocarbons or derivatives of hydrocarbons. The fact that the pigments Scarlet R and Sudan III, which have been used successfully in the over-production of epithelial proliferation, are also derivatives of hydrocarbons and closely related to the above agents is of added interest. The power of aniline and other hydrocarbons to paralyze the enzyme catalase has already been mentioned and is worthy of emphasis. Besides their effect on this "protecting" enzyme, hydrocarbons or their derivatives have been shown by Kastle,¹³ and by Kastle and Porch,¹⁴ to be powerful accelerators of peroxidase—the most important intracellular oxidizing enzyme found in practically all cells. May not such accelerators act on local cell enzymes, causing new powers of oxidation, growth, and division? By this acceleration of "growth" enzymes and the paralysis, or inhibition, of enzymes and anti-enzymes which control cell oxidations and growth rate—malignancy would be caused.

Symptoms and Signs from the Standpoint of Enzymes and Oxidations.—From the standpoint of our theory of cancer causation, a brief consideration of the most important symptoms and signs of cancer may be of interest. Cancer is usually associated with a rapid loss of weight and strength, and a secondary anemia is generally present. Often an acid intoxication resulting even in a coma similar to that of diabetes is found. The presence of lactic acid in the stomach contents in cancer of the stomach, or in cases of cancer in other parts, is recognized as being an important aid to diagnosis. It is interesting to note that Fletcher and Hopkins¹⁵ found that lactic acid formation is dependent upon the life of the muscles. With normal oxygen supply to the muscles they found no lactic acid formation, oxygen having even a destructive action on lactic acid. They emphasize their finding that lactic acid is not formed in dead muscles, but only in living muscles with reduced or absent oxygen supply. Araki¹⁶ also found that with oxygen starvation some of the lower animals form and eliminate abnormally large amounts of lactic acid. In each instance we believe these symptoms and signs of cancer are due to oxygen starvation of the body tissues in general because of the great demand in, and supply to, the tumor cells whose increased metabolism is using up large quantities of oxygen. The tumor is thriving in its aerobic life while the body is slowly starving because of the induced anaerobic conditions. The so-called avidity or hunger of the tumor cell is probably for increased amounts of oxygen.

Summary.—The writer has endeavored to formulate a new working hypothesis concerning the etiology of tumors in general and of cancer in particular. As stated in a former paper,² "the so-called enzyme theory is a compromise between the biochemical and parasitic theories which are in vogue at the present time. Cell or tissue injuries due to physical, chemical, or parasitic agents, or to functional or nutritional disorders are looked upon as essential 'precancerous' agents. While these injuries are potentially 'precancerous' they do not always result in malignancy; furthermore, they are not always apparent.

"The normal inflammatory process resulting from these injuries is the next step towards neoplasia. Thus, tumor formation is looked upon as closely related to normal cell proliferation and regeneration."

Attention is then drawn to the concentration and acceleration of normal intracellular oxidizing enzymes and co-enzymes in these areas of injury and inflammation. The catalytic effect of these enzymes is emphasized, and it is suggested that this "speeding up" of local cell oxidations leads to a marked increase in growth rate and of division rate—upon which the other characteristics of cancer depend. These new enzyme amounts and powers are transmitted naturally to the offspring of the cell or cells in which the change was initiated, and as a consequence, these newly acquired rates of oxidation, growth, and division become permanent, if not checked by the enzymes and anti-enzymes which protect the body against such injurious cell oxidations.

Included in this discussion consideration is given the nature and action of enzymes in general; and their relation to cell respiration, growth, and division is brought out. Finally, the important phenomena associated with cancer are examined from the standpoint of our enzyme theory.

Conclusion.—From theoretical study, and preliminary experiments² on white rats, the conclusion is reached (1) that cancer is the result of localized, unchecked over-combustion, or hyperoxidation, in epithelial cells; (2) that this condition is brought about by the concentrated, accelerated, and uninhibited action of intracellular oxidizing enzymes, or their co-enzymes, as a result of various injurious agents. Concerning the ultimate problems in tumors "it is evident that here as elsewhere in pathology we are dealing, not with independent problems, but with specific outlooks only on the wider field of general biology."

Congenital Tuberculosis.—Péhu and Chalié state that there are only 51 cases of congenital tuberculosis on record. They appear during or at the end of pregnancy when the placental circulation is established, and result from a bacillemia which is usually a terminal event. They should therefore be regarded as examples of transplacental contagion, and not of direct heredity.—*British Journal of Children's Diseases*.

SEQUEL OF A CASE OF TRIGGER FINGER.

BY ADONIRAM B. JUDSON, M.D.,

NEW YORK.

THE case of trigger finger which I reported in the *MEDICAL RECORD* June 13, 1914, progressed favorably to recovery. At the present time, two years and six months after the appearance of symptoms, and eighteen months after the date of the report, the affected joint, the principal joint of the right middle finger, is normal in every way except for a

FIG. 1.—A, a digital joint. B C, a tendon having its origin in the distant muscular mass in the fore arm, and its insertion in a phalanx. D D, Cylinders representing the sheaths which confine the tendons to the shafts of the diminutive long bones. Fig. 1 shows how in the hand muscular action produces exceptionally great interarticular pressure.

slight enlargement. Soon after the case was reported, however, arthritis appeared in a mild form in both thumbs and the principal joint of the right ring finger. There were characteristic jerks in these joints, especially the ring finger. They were however so slight and interfered so little with function, that if it had not been for the preceding history they would perhaps have passed unnoticed. Each of these digits has in turn recovered, except the ring finger, where the jerks persist, but without pain or inconvenience. This joint, however, is evidently so near entire restoration that the history of the case may be considered as closed.

I have explained the mechanism of this affection by saying that the hitching, corduroy-road action is produced by the presence of arthritic enlargements on the articulating surfaces. It may be said in criticism that other joints are not affected in this way by arthritis irregularities. In reply it may be said that no other joints show the peculiar arrangement of sheaths and tendons which is found in the hand, where the tendons run close to the shafts of diminutive long bones to which they are closely confined by unyielding fibrous sheaths. Here they run parallel with and close to the bones, so that a part of their force is wasted, or at least laid out, in pressing the articulating surfaces to-

FIG. 2.—A, the elbow joint. B C, the Biceps tendon. Fig. 2 shows how in the elbow, as in other joints as a rule, muscular action produces comparatively little interarticular pressure.

gether instead of giving motion to the joint and additional force to the grip. This is shown in Fig. 1. In joints like the elbow the force is chiefly expended in giving motion, with comparatively little interarticular pressure. This is shown in Fig. 2.

In my previous report this peculiar action is compared with that of a jack knife, where the square angle so obvious at the near end of the blade is a very positive irregularity on an articulating surface, while the steel spring concealed in the handle furnishes the powerful interarticular pressure. The result is a halting action, the true counterpart of trigger finger, correctly described as an arrest of motion followed by sudden acceleration.

The mechanism of recovery clearly follows the same lines, the elevation being reduced by absorption following attrition and continued pressure. This process of recovery may be imitated in the knife by filing down the corner of the square angle on the blade, when smoothness of motion takes the place of the jerk which attends opening and shutting a pocket knife.

The patient, the history of whose case is here concluded, continues to take oleum ricini, finding that the bad taste and smell are absent if *expiration* by the nostrils is carefully omitted (by no means an easy thing to do, but of the first importance), while the mouth is gently rinsed with any convenient liquid. It is surmised that by this treatment he may have escaped the digital deformity and disability so common in the aged. In this case however the oil is continued because it is part of the treatment of a disorder, of metabolism, considered incurable, for it is said: "Old age never comes alone."

In my opinion trigger finger not infrequently occurs without being recognized, although a severe case may for a time be attended by the pain and disability incident to arthritis. It may be considered as a curious incident occurring in the course of an arthritis which may or may not be serious. A case excites interest because the peculiar action, when well marked, is easily demonstrated and the deportment of the joint, involuntary and entirely beyond the control of the will, has more or less of the comical element. And when the question of mechanism comes to be considered, speculation and surmise have lead to interesting discussions and differences of opinion. The explanation which I have ventured may or may not be generally accepted.

53 WASHINGTON SQUARE.

A SYPHILITIC ROSEOLA LIMITED TO THE SOLES.

By DOUGLASS W. MONTGOMERY, M.D.,

SAN FRANCISCO, CAL.

THE roseola is the first and most frequent cutaneous manifestation of constitutional syphilis, and shows itself about forty-five or sixty days after the appearance of the chancre, as small delicately tinted rosy blotches on the sides of the trunk, over the abdomen, and on the flexors of the forearms. This eruption may occur in any situation whatever, but these are the most frequent sites, so frequent, in fact, that a syphilographer, in search of corroborative evidence of the nature of a venereal sore or of other suspicious circumstances, will involuntarily inspect the abdomen, flanks, and forearms. He will almost as involuntarily look at the palms and soles, for while this eruption is not so frequently seen here, when present it is more characteristic, and then usually includes both palms and soles. Years ago I had a striking instance of this in the person of a well known surgeon, who en-

tered my office and asked me abruptly, showing me his palms, if a rosy dotted rash there present could be caused by bichloride of mercury solution. I answered as promptly by requesting to see his soles. As the same eruption was found there, there was no further parley in regard to the nature of the symptom. Although in this case concomitant symptoms were found such as an insignificant chancre, amply justifying the diagnosis, yet the immediately convincing argument for the patient was the presence of this eruption in both situations. In the following case, however, the only situation in which a cutaneous syphilide was present was on the soles, and it was here so characteristic as to admit of no doubt as to its nature. Its value as a symptom was accentuated by the fact that the chancre was in an unusual situation, on the site of the right tonsil.

A friend referred to me for diagnosis a man with a brown dotted eruption on the soles, of recent appearance, free from all desquamation, and giving rise to no subjective symptoms whatever. He had a superficial pustular eruption widely and sparsely scattered over the cutaneous surface, and an inflammation of the lids and of the conjunctiva of the right eye. These two last symptoms were evidently pyogenic.

On examining his throat a fleshy rounded ridge was seen projecting above the level of the base of the tongue on the site of the right tonsil. This ridge was quite firm to the touch. Both tonsils had been removed five weeks previously. There was marked adenopathy on the right side of the neck in the neighborhood of the tonsil, and under the right side of the mandible. There was no adenopathy worth mentioning in the groin, and the epitrochlear lymph nodes were not demonstrable.

His temperature, taken by the mouth in the afternoon when I saw him, was 99° F. and his general health was very good. On this showing of the eruption on the soles, the induration at the site of the removal of the right tonsil, and the regional adenopathy, his physician ordered a Wassermann test, which turned out strongly positive. The further evolution of the eruption in this case was without special interest.

The first time I remember to have had my attention positively drawn to the occurrence of these roseolar eruptions in unusual situations was by Norman Walker, who mentioned a case that he had seen in Unna's clinic in Hamburg, in which the roseola was limited to the space between the shoulderblades. He remarked how easily such an eruption might escape observation—in fact, how difficult it would be to observe it, as the syphilitic roseola is commonly devoid of any subjective symptoms that would attract the patient's attention.

This fortuitous location of the roseolar syphilide is one of the reasons why spotted alopecia occurs only occasionally in early constitutional syphilis. This highly characteristic symptom is present only as a consequence of a foregoing papular or roseolar syphilide of the scalp.

These instances of slight or erratically situated eruptions of early constitutional syphilis are of special interest at the present time, because of the assertion made by some that early lues is so frequently free from manifestations on the skin or mucous membranes, and therefore runs its course as an entirely internal disease. There seems to be no doubt that this is true in some cases, especially in women, with whom the late tertiary lesions are frequently the only cutaneous manifestations observed. That, however, fifty or sixty per cent. of

syphilitic infections run their course without manifestations on the skin and mucous membranes, as reported by Stern, I do not think to be a correct statement of the case.

A word in regard to the time of infection in this case. There seemed no reasonable doubt that it was an instance of chancre of the tonsil. The infection, however, must have occurred previous to the tonsillectomy, which was performed only five weeks before. It is more likely that the chancre was present at the time of operation, and that its nature was misunderstood. In fact, the man had susceptible tonsils, as shown by persistently refractory and deeply eroding mucous patches of the site of the left tonsil, encountered during the course of treatment.

323 GEARY STREET.

THE MYSTERY OF THE ANTEFLEXED UTERUS.

By G. K. DICKINSON, M.D., F.A.C.S.,

JERSEY CITY, N. J.

CLINICAL medicine even at present is surcharged with the relics of the past. Whether it be in observation of conditions and theories founded on them, whether it be in the treatment of disease, or even in preventive medicine, there is a great deal that needs to be gone over in the light of scientific knowledge and unbiased judgment in order to come a little closer to actual truth. Careful investigation may present facts and wholesome common sense may prove them, yet reconstruction delays because nothing is more difficult than to rid one's self of the obsessions of the past.

Some see distinctly in the light of the dawn. They are those of broad minds, generally cultured, with many viewpoints, who have developed judicial intellect, while others (and they are in the majority), need the light of noon-day. Their brains move slowly and they feel the necessity of mental companionship, as it were, before accepting as proven changes which appear radical.

All through our medical literature we discover many points of fiction which have descended to us as a kind of sacred dogma, and to attack or alter these gives offense to many.

The topic of ante flexion of the uterus is just one of these bits of fiction. Those who read the literature broadly exploited by numerous writers cannot but be amused by their efforts to straddle two mounts. They attempt to plant one foot on facts and the other on elaborate symptomatology, on truth and fiction neither of which coordinate, and in these writings one invariably finds statements to the effect of a large exploitation of the syndrome that, to a beginner implies a distinctive lesion and a specific condition, with a hint that it is not quite true.

The best two books on gynecology are almost out of print. Emmett, 1884, though he speaks of an extreme degree of ante flexion frequently existing without producing the slightest inconvenience unless the organ becomes enlarged from some obstruction to its circulation and begins to prolapse, and though he says that for many years he has held the opinion that ante version is not a malposition and that no degree of the same would cause irritation unless the uterus failed to remain in a healthy condition, still goes on to give a symptomatology which he claims is that of an ante flexed uterus.

Skene, a peer in gynecology, 1889, gives eleven

pages to ante flexion of the uterus, its cause, symptomatology, and treatment. He prefaces his remarks, however, by saying that he considers ante flexion a deformity, that it is a disease of form rather than one of position. He claims that the physical signs and treatment all differ from those of the other displacements of the uterus and that a clear distinction should be made between the two, that is, the anterior and posterior displacements. Yet he, with others, divides ante flexions into two types; that due to imperfect antenatal development, often malnutrition, and that due to inflammatory lesions. He goes elaborately into the discussion of the symptomatology, that which leads to sterility and that which leads to dysmenorrhea, and suggests that an ante flexed uterus not properly relieved makes the woman liable to diseases of the Fallopian tubes and pelvic peritonitis, that the dysmenorrhea may increase in severity after marriage, the pain becoming intolerable, leading to a resort to opium, and eventually to an undermining of the health and moral tone. How poorly his etiology and pathology fit together!

Pozzi considers ante flexion as an exaggerated condition of the normal forward curve. He states that frequently a uterus in perfect condition is taken for one in a state of pathological ante flexion, and claims it is hard to draw a distinction between the physiological and abnormal position, holding that the abnormal begins when the examining finger perceives the angle as a sharp bend in the axis of the organ. He describes two forms, the congenital and the acquired, and enlarges on the symptomatology and specific treatment.

Bovée, with a larger horizon and with a courage of conviction somewhat unusual in medical literature, particularly in our dignified books, says that ante version has been stricken from the list of pathological conditions. He gives only a scant dozen lines to the subject.

Webster says it is impossible to determine what is the pathological angle of flexion. Nearly all degrees may be found in conditions of perfect reproductive capability and health. In some cases the most extreme ante flexion may be a congenital condition. Those acquired are most often due to uterosacral cellulitis.

Kelly and Noble, with their usual thoroughness of exposition, consider the matter with all carefulness and lean rather to the tendencies of the gynecologists, describing the position of the fundus and of the cervix, and their relation to each other in very minute detail. The symptomatology is described in full, and flexion, so-called, of the uterus, blamed for the symptoms and conditions coexisting. Dysmenorrhea and sterility are often taken as the distinguishing marks of pathological ante flexion.

Gilliam, a true gynecologist, to whom the uterus is a whole province, suggests that deviations and other conditions tangible to the touch produce genera and species on which to build a special science. His exploitation, with the exception of a change of words, reads as do the other articles in our literature.

In Kelly's Medical Gynecology is an excellent résumé of the same subject, which stands more firmly on the dogma that the flexion is pathological and that its pathology is the cause of the symptoms and conditions.

Crossen shows a still better understanding of the dual position, but more carefully states the etiology and the long-known fact, but not written

in Italics, that the symptoms are not due to the flexion but to complications which may arise, particularly some type of endometritis.

Polak speaks of flexion in the sense of an acquired condition rather than one of morphology. However, he does say that it is of pathological importance only when it causes symptoms of dysmenorrhea and sterility, laying the blame on the antelexion rather than on the circulatory or inflammatory conditions which may coexist.

From the few writers quoted can it not be discerned that with all endeavor to be scientific, the mind is pinned to that which is most objective—an apparent alteration in the position of the uterus and urgent symptoms? Is not the cart before the horse? Do we not see in all their writings that they comprehend the living pathology of this condition, yet fail to build up their articles, explain symptoms, and deduce treatment on this accurate knowledge of the pathogeny?

Malpositions of the uterus and even antelexion have been known for many centuries. The Papyrus Ebers, 1550 B.C., makes mention of prolapse of the womb. Hippocrates speaks of the different displacements of the womb that are frequently met besides those imaginary ones, such as fleeing of the uterus to the liver and to the heart.

Soranus, 200 A. D., notes that the ligaments of the uterus are weakened by inflammations and that the organ is then dragged upon and leans to the side, or all the ligaments may become weakened and the organ drop down.

Aetius, 600 A. D., gives an excellent account of antelexion and other displacements with their symptomatology, and describes methods of treatment, such as the knee-elbow position and the use of sounds.

Their observations were largely anatomical. Dissections of animals more often than of human beings gave them such knowledge as they possessed. And let it not be forgotten that the ancients were as bright, as intelligent, and as keen as the people living to-day, and that they possessed as logical minds and truthful diction as we accredit to ourselves.

In mammals above the monotremes, the ducts of Müller in early embryological life become united about the middle; the lower third forming the tube of the vagina, the middle, the thickened body called the uterus, and the inner or upper third, the Fallopian tubes.

Nature is not always perfect in her work. We have club feet, hare lip, cleft palate, strabismus, etc., etc., so in the womb we may have arrested development in whole or in part. We may have two uteri, or we may have a uterus with a septum, but, more commonly, the anterior portion does not grow as rapidly as the posterior portion, and we have, as a result, an accentuated curve in the uterine canal, so that there is seemingly a kink or an acute bending where the body and the cervix join.

These uteri are generally smaller and have a shorter canal than the norm. There being varying grades in this defect, the condition may demonstrate itself in the extreme in the so-called infantile uterus, and to a less extent in the types of antelexion.

As the uterus fails to develop and as this malformation is demonstrated, so we have to a greater or lesser degree defect in the development of the other sexual characteristics. Menstruation comes on later in life, is irregular and deficient. The mammary glands may fail to obtain a proper growth,

and the whole personale of the individual may be altered.

The uterus, biologically speaking, is a recent organ. Whereas the stomach, the liver and the kidneys come to us from low down in biological life, it is a recent acquisition, and, according to a well-known law, has not the resisting power to disease invasion nor the strong tendency to a perfect development that the older organs possess.

In the fetus and in early infancy the cervix is relatively much developed, while the body is still small and high, so, if the anterior portion of the uterus be retarded in development a seeming angle of acuteness occurs at the junction of the cervix and the body. If the uterus, which on digital examination seems to have this marked anterior curve, be removed and placed on the hand, it will be seen to be straight and without apparent defect.

Looking over the facts presented in this short paper we shall see that there are three periods in the study of the uterus: that of the anatomist who sees no pathology and attempts to describe the normal condition, rarely discovered; that of the gynecologist who does not see beyond his finger tip, and who through specializing narrows his mental horizon and may become a gynecological paranoiac, and that of the abdominal surgeon who has never described antelexion.

A study of these three periods will explain the mystery of the antelexed uterus—why it is that that which seemingly is tangible to the senses, particularly to that easily mystified one, the sense of touch, has led to observations, conclusions, and an exclusive dogma from which it is difficult to separate oneself.

We now know that antelexion is a deformity, that it is not a disease. Its symptomatology as written in the books is the symptomatology of the inflammatory conditions which a poor resisting organ cannot protect itself from, and is apt to be persistent (the same tendency which leads to a salpingitis when we have uterine myomata).

The symptomatology of antelexion, if it has one, is that of an imperfectly developed sexual characteristic, sterility, delayed and incomplete menstruation, imperfect development of the mammary glands, and the mental and physical states which are brought about by a failure of Nature to round out the female sexual system.

280 MONTGOMERY STREET

A CASE OF HERPES ZOSTER PRESENTING MULTIPLE SYMPTOMS AND AT ONE STAGE SIMULATING MASTOIDITIS.

BY JOSEPH WEINSTEIN, M.D.,

NEW YORK

THE following report of a case of herpes zoster is submitted with no attempt at classification, but rather to call attention to the multiple symptoms presented:

F. Z.—Female, 20 years of age, single. Jan. 8, 1915, was taken ill about two weeks ago, complaining of malaise, headache, and sore throat. Was up and about all the time; attack gradually subsided and patient felt fairly well up to the date when she began to have chills and fever, general pains in the limbs and back, and severe pains in the head, especially behind the ears.

Examination showed a well nourished and well built girl; face flushed, body warm, skin dry, tongue heavily coated, mouth mucous membrane of good color, throat red, with the appearance of a subsiding inflammation, no follicles; palpation elicited no tenderness

or fluctuating masses on either side; eyes bright, pupils normal; exquisite tenderness and edema over both mastoids. Examination of the lungs, heart, abdomen, and extremities gave negative results. No leucocytosis. T. 102.2°, R. 26, P. 130. (Subsequent Widal, diazo, and blood examinations were negative).

Diagnosis: Subsiding tonsillitis and pharyngitis, with possible bilateral mastoiditis, probably of influenzal nature.

Jan. 9. Edema over mastoids slightly less, tenderness the same. T. 102.8°, R. 24, P. 130. Jan. 10. Complained urgently during the night of pains in the right side of the head over the frontal and mastoid areas. Patient was cared for by the family physician until January 11, when Dr. Reitzfeld referred her to me. I found both drums normal, excluded mastoiditis, and urged expectant plan of treatment. However, I made no diagnosis. January 12. T. 100°, P. 100. Distinct blush over face (supraorbitally located), redness and edema of right eyelid; small cluster of vesicles at edge of blush, another at tip and inside of right nostril. The edema did not pit on pressure and the underlying tissues were only slightly sensitive. Patient complained of burning and itching, but felt generally better. January 13. T. 99°, R. 22, P. 96. The edema has extended to right cheek; frontal area practically free; both lids swollen, lower lid especially so; eye almost closed; tenderness over mastoid has disappeared; blush has disappeared; vesicles are beginning to dry up. Patient still complains of burning and itching. January 14. Patient considerably better; edema of right cheek and lids disappearing; vesicles drying up. Pharynx and throat normal.

The reference below are taken from an exhaustive paper, "A Further Contribution to the Herpetic Inflammations of the Genuiculate Ganglion," by Dr. J. Ramsey Hunt (*Am. Jour. Med. Sciences*, August, 1908), and are numbered in order to facilitate reference in summarizing the writer's case.

1. "Herpes zoster is an acute specific infectious disease characterized by an inflammatory reaction in ganglia containing the so-called spinal or unipolar type of cells. Ganglia of this type are the spinal ganglia of the posterior roots, the Gasserian and geniculate ganglia of the cranial nerves. The essential pathological lesion is generally limited to a single ganglion which corresponds to the eruption of zoster.

2. "That more than one ganglion may be involved is shown clinically by the occurrence of double, triple, bilateral, and alternate forms of zona, the eruption appearing in more than one zoster zone. This tendency to involvement of more than one ganglion is especially frequent about the head and neck. I would call special attention to the fact that clinical evidence exists showing that some ganglia may be implicated in zona without the occurrence of an eruption in their respected zones.

3. "In zona the ganglion which corresponds to the eruption is to be regarded as the chief or eruptive focus. The inflammatory reaction is not confined solely to this ganglion, but inflammatory changes of a milder grade may be present in an adjacent ganglion above or below. In other words, there may be serial involvement of ganglia, the extent and intensity of which depends upon the severity of the infection. The Gasserian, geniculate, and upper cervical ganglia may be regarded anatomically as representing a more or less continuous ganglionic chain.

4. "If the Gasserian and geniculate ganglia by virtue of the unipolar cell type belong to that series of ganglia liable to the inflammation of zona, the same would also be true of the ganglia of the glossopharyngeal nerve and of the vagus nerve. These ganglia are also regarded by histologists as belonging to the unipolar or spinal type, and, therefore, cannot be excluded from the realm of herpes zoster.

5. "I regard the Gasserian, geniculate, acoustic, glossopharyngeal, vagus, second, third, and fourth cervical ganglia as representing a continuous ganglionic series or chain, all having the same embryonal origin (neural ridge), and all with the exception of the acoustic ganglia having the same cell type (unipolar), and therefore belonging to the realm of posterior poliomyelitis. A hemorrhagic inflammation in one of these ganglia is followed by the usual manifestation of herpes zoster, an eruption appearing in its respective zone. Depending upon the severity of the infection other ganglia of the group may be the seat of an inflammatory reaction as well, but not sufficient in degree to produce an eruption."

Summary.—In the case under discussion, the first local symptoms were present in the throat. The patient did not seek medical advice during this period. After an interval of two weeks during which the patient was "fairly well," and the "sore throat" had subsided, she began to complain of pain in the head and especially behind the ears. At this stage medical advice was sought and an examination disclosed a subsiding inflammation in the throat, and tenderness and edema over both mastoids followed within forty-eight hours by severe pain in the mastoid and frontal regions. The following day the edema had extended to the frontal region involving both eyelids of the right eye and vesicles appeared in this region.

It is suggested that what appeared when first seen to be a subsiding tonsillitis and pharyngitis may have been a primary involvement of the ganglia of the glossopharyngeal or of the vague nerve. (Ref. 4 and 5 above.) It could not be ascertained whether an eruption of zoster was present at any time during this period. Assuming the infection to have been primary in the ganglia of either of these nerves, it would seem that an infection severe enough to have subsequently involved adjacent ganglia would have caused an eruption in its own area, which may have been the case.

The secondary symptoms appeared in the mastoid region. Whether this indicated an involvement of other ganglia of the chain (geniculate, second, third, or fourth cervical ganglia, Ref. 5) or were simply referred symptoms, the writer is not prepared to say—no eruption appeared in either area. It is to be regretted that owing to the severe illness of the patient no functional tests were made. (Ref. 2.)

Buys (Bull. Soc. Belge d'Otol., de Laryngol. et de Rhinol., 1898) reports a case of a girl, 17 years of age. Onset with vomiting, severe headache, stiffness of the neck, photophobia, no fever or delirium, pulse slow and irregular. Severe pains subsided after the fourth day, and settled in the mastoid region of the right side, which was very tender. Hearing was diminished, vesicles made their appearance on the fifth day on the antitragus, and lobule of the ear. On the sixth day a fresh crop appeared on the mesial surface of the pinna and the lobule. All pain disappeared within a few days' time. Except for the fact that symptoms were early present in the neck in this case and in the "throat," in the writer's case, and in both instances settled in the mastoid region later, there is no similarity between the cases. Hunt, in referring to the above case, says: "The frequent vomiting and slow irregular pulse, in this case, are strongly suggestive of a vagus disturbance. I would also emphasize the area of distribution of the eruption corresponding to the cutaneous filaments of the vagus." With the

appearance of the eruption in the Gasserian region, a first diagnosis of zona was made. That a severe inflammation was present in this region seems indisputable, all of the symptoms of herpes zoster being present.

The possibility of the infection being limited to this ganglia only, the earlier symptoms having no connection, except possibly toxic in nature, also suggests itself to the writer. The case seems of sufficient interest to report and a discussion of it is invited.

261 CENTRAL PARK WEST.

PERICYSTITIS COMPLICATING ACUTE APPENDICITIS.

By EUGENE H. EISING, M.D.,

NEW YORK.

PERICYSTITIS is inflammation of the areolar connective tissue surrounding the bladder. This condition is always secondary to some neighboring suppurative focus. The inflammation usually extends from suppuration in the prostatic urethra, the prostate gland or prevesical space. The infection of the bladder wall is marked by sharp symptoms of vesical stranguary which were absent in the parent infection. The process rarely leads to destructive changes in the bladder. Its cure consists in removal of its primary cause.

Among the various manifestations produced by the inflamed appendix is the symptom train of pericystitis, which may be of such severity as to mask entirely the initial disease in the appendix.

Two such cases have been observed by me. The records of the first case are unfortunately no longer at hand.

CASE I.—In the first case there was hematuria and cystoscopy revealed an unusual picture that suggested carcinoma. A transperitoneal operation was planned and a gangrenous appendix was found intimately adherent to the posterior wall of the bladder and involved with it in a mass of adhesions. Even at the operating table it was by no means apparent that the primary focus of the disease was in the appendix, and only after considerable dissection did it become evident that the condition of the bladder wall was the result of secondary involvement. The bladder symptoms subsided at once after the removal of the appendix.

CASE II.—The second case was seen in May, 1915, through the courtesy of Dr. Morris of Brooklyn. The patient was a man of 23 years, in the third day of his present illness. There had been nine similar attacks between October, 1910, and May, 1915. These attacks lasted from three to ten days, and were characterized by sudden severe abdominal and vesical pain, always provoked by an attempt at urination. The abdominal pain became less intense, but the vesical tenesmus remained severe. In two attacks there was vomiting. Urination was frequent and painful, and several times blood was passed. No pus was ever found in the urine. With rest in bed and medication these attacks had always subsided. During the intervals the patient was entirely well.

The patient was thought to be suffering from calculus either in the lower part of the ureter or in the bladder. Cystoscopy showed an area of about 4 cm. in circumference of intense injection, upon the right side behind the ureter and extending to the median line. This area was studded with small vesicles (bullous edema) containing clear serum. The area of injection faded rapidly toward the periphery. A catheter passed readily into the right ureter and clear urine was obtained. Twice in prevesical abscess I had seen marked bullous edema of the bladder wall underlying the space of Retzius, and in view of these experiences it seemed probable that the source of trouble lay outside of the bladder.

Examination of the right iliac fossa revealed a rigid rectus muscle and a very distinct area of tenderness lay

well toward the median line. Although the area of tenderness was not in the usual place for the appendix, it seemed to explain better than any other hypothesis this unusual train of symptoms.

Two days later appendectomy was performed. The *caput coli* seemed congenitally misplaced toward the median line. The appendix was found well down in the pelvis. It was gangrenous and imbedded in a mass of dense adhesions firmly adherent to the posterior wall of the bladder. Convalescence was uneventful. The cystoscopic picture has now returned to the normal, and the patient has since remained free from any of his former symptoms.

These two cases demonstrate a complication of acute appendicitis which if not borne in mind may lead to serious diagnostic error.

35 WEST EIGHTY-FIRST STREET.

Medicolegal Notes.

Insurance Against Assistant's Mistakes.—An insurance company insured a physician, who had in his employ two younger doctors as assistants, against loss from liability for bodily injuries or death suffered in consequence of error, mistake, or malpractice by any assistant in his employ "while acting under the assured's instructions." One of his assistants made a mistaken diagnosis in an accident case, resulting in a judgment for damages against the physician. The assistant diagnosed and treated the patient without suggestion or aid from the physician, who apparently had no knowledge of the particular case and gave the patient no personal attention; the assistant merely acting according to previous general instructions and the custom which prevailed under the contract between himself and the physician. In an action on the policy it was held that the insurance company was not liable, since the quoted words were intended to qualify its liability, and if they were treated as covering the physician's general instructions, they would neither expand nor restrict the insurer's liability, but would be altogether meaningless.

"In a physician's contract such as the one before us," the court said, "the learning, experience, and ability of the individual insured necessarily and largely enter into the consideration. The risk assumed is the assistant 'while acting under the assured's instructions.' As a safeguard against the error, mistake, or malpractice of the assistant, the insurer stipulates for the instructions of the assured. The insurer, relying on the professional skill of the assured, contracts for his supervision or at least for his instructions. It cannot be held that the insurer by this sort of contract undertakes to answer for the mistakes or malpractice of a doctor's helper acting on his own responsibility, without any advice or directions from the assured; such subordinate being unknown to the insurer, and the policy without provision as to his qualifications. This would be an extraordinary hazard, and not one within the purview of this policy."—*Seay v. Georgia Life Ins. Co.*, Tennessee Supreme Court, 179 S. W. 312.

X-Ray Photographs in Evidence.—In an action for damages for injuries to the plaintiff's neck by falling in front of moving cars, objection was made to the introduction of x-ray photographs of the plaintiff's neck and of testimony of a Dr. Gist explaining them. Dr. Vineyard, the owner of the x-ray machine, who made the photographs, had testified very fully as to his experience in such work, and it was shown by the witnesses that the photographs correctly represented the condition of the plaintiff's neck. The court thought a sufficient predicate was laid for the introduction of the photographs, and there was no error in admitting them. It saw no objection to the testimony of Dr. Gist in explaining the photographs and showing the bones which were exhibited thereby and in explaining what bones were named in the testimony. It thought it would be an aid to the jury in understanding the testimony of the witnesses as to the bones which were claimed to have been injured by the plaintiff and denied by the defendant. All that is required for the introduction of a photograph of this kind is that preliminary evidence should be given of its correctness.—*Pecos & N. T. Ry. Co. v. Winkler*, Texas Court of Civil Appeals, 179 S. W. 691.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery

New York, January 29, 1916.

REPORT OF THE SURGEON GENERAL OF THE UNITED STATES NAVY.

THE report for the fiscal year 1915 of the Surgeon General of the United States Navy has been issued recently. During the year under review there has been an increase in the admission and death rates over the preceding year. The death rate, however, is still very low, only 4.18 per 1,000, and the admission rate is lower than for the 10-year period 1901 to 1910. The Surgeon General therefore believes that considering these statistics include the time of the Vera Cruz campaign, during which a large proportion of the personnel was occupied in tropical duty, the above result may be pointed out as fully satisfactory and up to the high standard of the past several years. Among the major classified groups of diseases that show an increase in total damage are the following: Diseases of the digestive system, of the ear, of the genitourinary system, of the nervous system, of the respiratory system, diseases of infective type, and wounds of all classes. With regard to typhoid fever the Surgeon General states that he has no hesitation in saying that the practical elimination of typhoid fever from the Navy is due almost entirely to prophylactic inoculation. He further draws attention to the fact that reports from the armies of the contending nations now in the field show remarkable improvement so far as the diminution of typhoid fever is concerned. The Germans, who had provided extensive hospital accommodation for expected or possible incidence of typhoid, measured by standards of previous conflicts, have been able to convert these facilities to other uses owing to the comparatively slight incidence of what was once one of the worst scourges of a military campaign. In the British Expeditionary Force in France during the first ten months of the war the ratio of morbidity was 14 times, and that of mortality 42 times greater among the uninoculated than among the inoculated. The sanitary condition of the French army has been particularly satisfactory. No epidemics have appeared, thanks to the knowledge and strict application of the fixed laws of hygiene. That a few isolated cases of typhoid fever did appear was because those who were attacked had not been protected by vaccination, or had been vaccinated in an unsatisfactory manner as to quantity or method of application. In the early months of the war, when pre-

ventive vaccination had not yet been made general, and numerous cases were being received in the infectious hospitals, it was thought that cases of typhoid fever had been found in those who had been vaccinated. This was not so. Those cases were found to be paratyphoid.

As regards the venereal diseases, the bane of all military aggregation, the report states that during the past year the primary admission rate for venereal disease was more than for the year 1913, but below the rates for 1909, 1910, 1911, and 1912. The results of venereal prophylaxis are dealt with, and it is noted that while efforts were made toward the adoption of a system of compulsory prophylactic treatment against venereal disease in 1907, the matter was not generally taken up throughout the Navy until January, 1909. It is difficult to draw conclusions from the figures regarding venereal disease. The tables in the report at first sight do not appear to be in the least encouraging, rather the reverse, but several facts must be taken into consideration. It would seem from a cursory survey of these tables that coincident with the adoption of the system of venereal prophylaxis the admission rate of certain diseases was nearly or more than doubled. It is consequently necessary to explain that in the early part of 1909, a new statistical report was adopted, and this statistical report directed that all cases of venereal disease that appeared for treatment should be admitted to the sick list for purpose of record, even though it was not necessary to excuse the men from duty and admit them to the sick list for treatment. In drawing conclusions from the statistical evidence adduced, as to the value of venereal prophylaxis, it appears proper to point out that failure to prevent the disease is due in most cases to the fact that preventive measures by means of antiseptics are so long delayed that the virus is taken up by the lymphatics and carried beyond the reach of the antiseptic agents by the time they are applied.

Tuberculosis in the Navy has decreased. Malaria, owing to the continued presence of a considerable part of the Navy in Mexican waters, shows an increase of 50 per cent. of admissions over 1913. Sanitary conditions afloat are generally fairly satisfactory. The greatest stumbling block in the way of wholly satisfactory hygienic conditions is efficient ventilation. The ventilation problem is by no means solved ashore, and, of course, on shipboard, and especially on warships, the problem presents itself in its most complicated forms. Notwithstanding the inherent difficulties of the situation, the Bureau of Construction and Repair has achieved excellent results, and the question of an adequate air supply on board war vessels bids fair to reach a solution which will tend to conserve the health of the Navy personnel.

The Surgeon General reiterates his complaint of the previous year that the present size of the Medical Corps is entirely inadequate for service requirements, and should be increased for a peace-time basis. There is also a lamentable shortage of officers in the Medical Reserve Corps and likewise of chief pharmacists and pharmacists in the Hospital

Corps. The report goes to show that the health of the Navy is well cared for, but it also shows that from this standpoint matters would be better if the Medical Corps as a whole was kept up to its full strength. If the efficiency of the Navy is to attain the highest standard, the greatest generosity must be observed in all measures relating to prevention and treatment of disease.

PHYSICAL EXAMINATION OF THE BLOOD SERUM IN CARDIAC AND RENAL DISEASE.

THE present methods of study of renal insufficiency involve metabolism researches that demand much time and ample laboratory equipment and are impossible of routine application under ordinary circumstances. Since the content of protein and salt and water in the blood serum varies in a fairly definite manner, depending upon the action of the heart and kidneys, Butterfield, Erdwurm, and Braddock (*Am. Jour. Med. Sci.*, 1916 cli, 63) were led to use purely physical methods in the study of this fluid in the attempt to detect deviations from the normal. The depression of the freezing point was taken as a measure of the concentration of relatively simple molecules irrespective of their nature; the refractive index was used to detect variations in the protein content, while the specific gravity was of aid in the recognition of hydremic or concentrated sera.

They studied a number of clinically typical cases by these methods and obtained some very interesting results. In normal individuals the figures were found to be quite constant. In cases of cardiac decompensation with edema the findings did not vary beyond the normal limits showing a retention of all the elements of the blood serum and not merely a dilution of the serum. In chronic nephritis with edema the freezing point depression was normal while the refractive index and the specific gravity were both much lower than normal. This indicates a diluted or hydremic serum, the dilution being not with water alone but with salt also. In cases of chronic nephritis with uremia the depression of the freezing point was much greater than normal while the refractive index and specific gravity were but slightly increased. This indicated a concentration of the serum, especially with the simpler molecules. In chronic nephritis with uremia and edema the picture was a composite one showing increased depression of the freezing point and a lowering of the refractive index and the specific gravity. In still another group of cases, those of arteriosclerosis with hypertension, the depression of the freezing point was normal while the refractive index and the specific gravity were both much increased, evidence of a marked concentration in the serum. Ten to 15 c.c. of serum are said to be sufficient for the tests which require but a short time for their performance.

Certainly, in the typical cases reported, the differences are such that a classification is easy on the basis of the figures presented. The authors state that it is necessary to find out how slight a deviation from the normal may be detected by these tests before a full realization of their value can be

reached. In the fully developed cases they offer a diagnostic method that should eventually prove of great help in therapeutics. It should be borne in mind that the technique of the tests, while not at all complicated, nevertheless requires a nice attention to detail and adherence to method that is indispensable for accurate work. It is to be hoped that this work will be continued, for it offers much both in the field of diagnosis and in that of therapeutics.

AORTOTOMY IN EMBOLISM OF THE ABDOMINAL AORTA.

NEARLY all the recent books on surgery devote some space to a description and illustration of the technique of removal of emboli from the pulmonary artery, as advocated by Trendelenburg and brought to the attention of American surgeons by Willy Meyer (*Trans. Am. Surg. Asso.*, xxxi, 1913), although the operation has never yet been permanently successful in man. In the operation for pulmonary embolism the necessary compression of the ascending aorta and pulmonary artery must not exceed forty-five seconds and the removal of a large embolus must be accomplished within a very few minutes after its lodgment or the case is absolutely hopeless. In embolism of the abdominal aorta, however, operation has been successful in at least one instance, and the indications are so clear, the point of impaction of the embolus so accessible, the time at the disposal of the surgeon so relatively ample, and the technique so comparatively simple, that the subject deserves attention. The latest report of aortotomy for the removal of an embolus from the abdominal aorta is that by Konjetzny (*Zentralblatt f. Chir.*, No. 42, Oct. 16, 1915). As he says, embolism of the abdominal aorta with wedging of the embolus at its point of division into the iliac arteries is not extremely rare. Suddenly appearing and very severe lancinating pains in both legs, accompanied by loss of motility and sensibility, together with absence of pulsation, pallor, and coldness in both legs constitute the symptom-complex of this easily diagnosed condition. The course and prognosis are always the same—gangrene of both lower extremities and death sooner or later.

Konjetzny's patient was a shipbuilder, 43 years of age, a well-built, well-nourished man, who previously had apparently always been in good health. In connection with a severe cold which he had contracted three days before, he was suddenly taken with severe lancinating and tearing pains in both legs. These pains were so severe as to be hardly endurable, and at the same time there developed complete loss of sensation and motion in both legs. The legs were at first entirely pallid but after awhile the upper portions of the thighs became bluish. Both legs felt cold from the beginning. Thirty-six hours elapsed before the patient was taken to the surgical clinic. Upon admission, the patient's face was pale, heart sounds very faint but with no murmurs, pulse irregular and weak. Examination of the lungs and abdominal organs showed nothing of especial significance. Both legs were cold as far as the inguinal region, paralysis

was complete, the pulse could not be felt in the femoral or popliteal arteries, and the diagnosis of wedging of an embolus at the bifurcation of the aorta was unquestionable. Since the condition had already existed for thirty-six hours, a favorable result after operation could hardly be hoped for, but because of the otherwise hopeless nature of the case immediate operation was undertaken. After exposure of the affected section of the aorta, palpation disclosed a large plug in this vessel and extending continuously down both iliacs. The aorta was isolated, clamped about 10 cm. above its point of division with a Doyen clamp sheathed in rubber tubing, and an incision about 3.5 cm. long was made in the vessel, running to near its point of bifurcation. The slightly adherent embolus was easily expressed through this incision and was found to be about 5 cm. long and of a brownish red color. To this was joined a dark red coagulum which filled the iliacs and accessible portion of the femoral arteries. After all these coagulated masses were pressed out through the wound in the aorta, this was closed by suture, the clamp removed, the peritoneum sutured over the vessel, and the abdominal wound closed. At this point good pulsation could be noted in both femorals. This good result was, however, only temporary, and a short time after the operation pulsation in the femorals could no longer be felt. The heart became progressively weaker and the patient died three days later. Autopsy showed that there had been an old myocarditis, and that at one portion of the wall of the left ventricle there was a tolerably fresh thrombus, doubtless the source of the embolus. The aortic suture had held completely tight, and there was no thrombus formation at that point nor in the adjacent segments of the common iliacs; whereas the external iliacs and femorals, with their veins, were filled with clotted blood.

In reviewing this case and comparing the history and post-operative course with that operated upon successfully three hours after the onset of symptoms by Bauer (see MEDICAL RECORD, Jan. 17, 1914), it is seen that the symptoms in the two cases were almost absolutely identical, though Konjetzny's patient was in much better general physical condition than Bauer's. It is probable, therefore, that if Konjetzny's patient could have been operated upon within three hours instead of at the end of thirty-six hours he also might have been saved. It is evident that in order to be successful it is essential that operation should be undertaken as soon as possible, before progressive clot formation has taken place or changes have occurred in the intima of the peripheral vessels. The symptom-complex is so pathognomonic that there should be no hesitation in making the diagnosis; and since in this condition medical measures are totally impotent and too much delay means gangrene of the extremities and death, it is apparent that no time should be lost in making the operation. Early operation should save the majority of these patients who, without operation, are doomed.

HAS OUR CONTROL OF SYPHILIS REALLY ADVANCED?

A GENERATION ago we were fairly well pleased with our treatment of syphilis, and were accustomed to rank the latter among the few diseases which we

could really control by medication alone. Then in the fulness of time we received the benefits of several startling discoveries, to wit: the spirochete, Wassermann reaction, and salvarsan. Our resources against the disease are multiplied and our control over it is increased many fold. But strangely enough the reactionary now appears and disputes the spirochete etiology, the reliability of the Wassermann reaction, and the value of salvarsan. For him, perhaps, these discoveries have really interfered with the proper development of our knowledge of the disease. In a word, these supposed advances are much too good to be true. While we are not inclined to sympathize with these reactionaries, and rather doubt their sincerity at times, we have to give due heed to certain polemic articles which are put forth in good faith. Professor Bruhns of Charlottenburg (*Berliner klinische Wochenschrift*, October 12) devotes much time to the Wassermann reaction, citing many examples to warn against reposing too much confidence in the finds, when the interval covered is relatively brief. The principle of the reaction is not antagonized but in all negative finds it must be persistently followed up—for years if need be. In the long period of latency between early and late syphilis, a negative reaction means nothing at all. In regard to the efficacy of medication this can be determined, he says, only by decades—not years—of treatment.

TRUE PSORIASIS OF THE BUCCAL MUCOSA.

FOR many decades it was almost an aphorism that psoriasis vulgaris was purely a malady of the integument. Although all rules must apparently have paradoxical exceptions, and although most exanthems and eruptions have, perhaps only in very rare cases, shown participation in some of the mucosæ, psoriasis has been regarded as something so native to the skin that it could not occur in any other locality. Those who describe such a condition as psoriasis linguæ are careful to state that it is not the same affection as psoriasis of the skin. Despite the enormous negative experience of clinicians, positive cases may come along under a great variety of circumstances, and it is often the expert who is unable to place them because he is so unescapably convinced of their non-existence. Apparently psoriatic lesions of the mouth have masqueraded under the general term leucoplakia. At a session of the General Medical Society of Cologne last March (*Münchener medizinische Wochenschrift*, October 19, 1915), Albersheim presented a case in which by exclusion he had arrived at a diagnosis of psoriasis of the buccal mucosa. The young woman patient gave a negative Wassermann reaction. The supposed psoriasis was seated on the mucosa of the left cheek and had every appearance of cutaneous psoriasis. In discussion, Dreyer, a believer in mucosa psoriasis confirmed the diagnosis, and prophesied that a microscopic section would show the typical histological structure of cutaneous psoriasis.

WAR NEPHRITIS.

THE outbreak of diseases in select material like soldiers should throw light on the same diseases as they attack the underfed, anemic subject in peace times. This should be especially the case when the men are attacked by wholesale. At a session last fall of the Imperial-Royal Medical Society in Vienna (*Berliner klinische Wochenschrift*, No-

vember 15) Klein and Pulay described an outbreak of hemorrhagic nephritis accompanied by mild fever, prostration, and edema. The apparent causes were in part given as angina, mild scarlet fever, and exposure, all well recognized causal agencies. In a study of the urine the *B. coli* was found in pure culture. This organism may cause nephritis by direct extension, or lymphatic or hematogenous infection, but only after a kidney has been previously damaged. In these cases pyelitis may be latent. In several fatal cases the presence of old nephritis explained the situation, although death was not uremic but septic. The authors believe that the *B. coli* was the efficient cause in many, if not most, of the cases.

News of the Week.

Health of the Canal Zone.—The report of the Department of Health of the Panama Canal for the month of November, 1915, begins with the so often repeated statement: "No cases of yellow fever, smallpox, or plague have originated on or were brought to the Isthmus during the month." Among employees, numbering over 34,000, the total number of admissions to hospitals and quarters was 887, a rate of 311.01 per 1,000. As compared with 294.80 for the preceding month, and 298.93 for the corresponding month of last year. The total number of deaths from all causes was 23, of which 17 were due to disease, or 5.96 per 1,000, as compared with 5.39 for the preceding month and 1.61 for the same month of 1914. All the deaths from disease were among the colored employees; four were due to pneumonia and the rest to various chronic ailments. The total admission rates for malaria, hospitals and quarters, was 22.09, as compared with 34.11 for October, and 69.08 for November, 1914. This is the lowest rate ever attained on the Isthmus at any season. There were no cases of typhoid fever during either October or November. For the Canal Zone, the death rate from disease for the month was 11.14 per 1,000, and the birth rate 20.75; for Panama City, the rates were 27.63 and 50.29 respectively; and for Colon 20.87 and 24.55. The sanitary work of the Canal Zone was continued, the heavy rains during the month making it possible to note the points in the drainage systems in the several districts which need additional permanent work. The annual physical examination of school children was made during the month, 1,002 children being examined.

Typhus in Mexico.—A party of American physicians is expected shortly to go into Mexico to study conditions there as regards typhus fever, of which, it is said, there are now at least 100,000 cases. The party will be headed by Dr. Carlos Husk, chief surgeon of the American Smelting and Refining Company, it is reported, and will include, among others, Dr. E. Libman, Dr. Peter Olitsky, and Dr. Bernard S. Denzer, all of Mount Sinai Hospital, New York.

D. D. S. Columbia.—Columbia University has under consideration a project to establish a dental school on a highly scientific and educational plane. The Medical Faculty has already approved of the plan, and it is proposed to ally the new school of dentistry closely to the medical school, requiring the same standard of fitness and previous academic training for admission to both. For the first two years the program of studies in the

school of dentistry will be the same as that in the school of medicine, the last two years being devoted entirely to dental practice.

Red Cross Day.—Wednesday, January 27, was designated by President Wilson as a day for special contributions to the Red Cross for the relief of the warring countries of Europe.

State Census.—According to the census taken by the State last June, the population of New York State on July 1, 1915, was 9,687,744, of whom over 52 per cent., or 5,047,221, were in New York City. The number of inhabitants in the State has, according to this estimation, increased 20.86 per cent. during the last ten years, while in the city the increase has been 25.7 per cent. The Federal authorities have, however, declined to use this enumeration, which had already been protested by the City Department of Health, and have informed Commissioner Emerson that in their computations they will use the 1910 census figures by which the estimated population of the city on July 1 was 5,602,841. The police census, taken last fall, resulted in an estimated population of 5,585,772.

City Death Rate High.—During the week ending January 15, there were reported in New York City 1,863 deaths, as compared with 1,612 deaths reported during the corresponding week of last year, making the death rate for the week higher by 1.87 than that for the third week of 1915. The increased mortality was due almost entirely to influenza and pneumonia and to the effect of these two diseases on other causes of death which showed appreciable increases, such as heart disease, pulmonary tuberculosis, and Bright's disease. The acute infectious diseases showed a slight decrease, and there was a marked decrease in the deaths of children under five years of age. Of the respiratory diseases, influenza caused during the week 90 deaths as compared with 10 during the same week of 1915; acute bronchitis, 19 deaths in 1916, and 21 deaths in 1915; bronchopneumonia 109 deaths in 1916, and 122 in 1915, and lobar pneumonia 224 deaths in 1916 and 168 deaths in 1915, making a total of 442 deaths due to these diseases during the week as compared with 321 for the same week of last year. The death rate for the first three weeks of 1916 is 16.64, while for the same period of 1915 it was 15.31.

Decrease in Rabies.—Statistics for the last four years recently made public by the Department of Health show a marked decrease in the occurrence of rabies in New York City. The figures are as follows:

	1912	1913.	1914.	1915.
Total dog bites	4,599	4,592	4,640	3,648
Deaths from dog bites	6	8	8	1
Victims treated at clinics	452	529	509	279
Dogs found with rabies	239	159	318	103

The Health Department feels that if the campaign against the disease can be as vigorously prosecuted and the same rate of progress maintained, rabies in the city will soon be stamped out.

Dies at 103.—Mrs. Hannah M. Towar of Detroit, who celebrated her 103d birthday last November, died of the grip on January 19. She was born in New York but had lived in Detroit for over sixty years.

Tuberculosis Preventorium.—At the annual meeting of the Tuberculosis Preventorium for Children, held on January 18, Dr. Hermann M. Biggs, president of the institution, announced that

during the past year 678 children from four to fourteen years of age were cared for with marked improvement in all cases. All the officers of the society were re-elected.

Trudeau School of Tuberculosis.—It has been decided to offer courses in the advanced study of tuberculosis at Saranac Lake in the Trudeau Sanatorium (Adirondack Cottage Sanitarium) founded by Dr. E. L. Trudeau in 1884, and the nearby New York State Sanatorium at Raybrook, and in association with the Saranac Laboratory, the Reception Hospital and the Sisters' Hospital at Saranac Lake, as well as the Stony Wold Sanatorium at Lake Kushaqua. A prospectus and schedule of the course of study can be obtained from the secretary, Saranac Lake, N. Y.

Personals.—Sir WILFRED GRENFELL, medical missionary in Labrador, is now serving as a major with the Twenty-second British Expeditional Hospital near the front in France.

Dr. RAY LYMAN WILBUR was installed on January 22 as president of the Leland Stanford Junior University, San Francisco. Dr. Wilbur was for several years dean and professor of medicine in the School of Medicine of the University.

New Maternity Department.—At the January meeting of the Board of Managers of the Norwegian Lutheran Deaconesses' Home and Hospital, Brooklyn, N. Y., it was decided to establish a department of obstetrics in which shall be cared for all the hospital cases of childbirth and diseases of pregnancy. The department will be housed in the new addition to the hospital which is practically completed, and it is expected that patients will be received soon after April 1. At the same meeting, Dr. Robert E. Coughlin was appointed attending obstetrician to the hospital.

Letchworth Village Needs.—In the annual report of the Board of Managers of Letchworth Village, the New York State institution in Rockland County for the feeble-minded and epileptic, attention is called to the need for extending the plant by the erection of four additional dormitories to provide for 280 patients, the completion of the "improvable boys' groups," and the building of a storehouse. The inmate population is now 300, and is expected eventually to be nearly 3,000.

Medical Society Elections.—NEW YORK PATHOLOGICAL SOCIETY.—At the anniversary meeting of the society, held on January 12, Dr. Francis C. Wood was elected president and Dr. J. Gardner Hopkins, secretary and editor of the Proceedings.

AMERICAN ASSOCIATION OF ANATOMISTS.—The following officers were elected at the New Haven meeting held recently: *President*, Dr. Henry H. Donaldson, Wistar Institute; *Vice-President*, Prof. Clarence M. Jackson, University of Minnesota; *Members of the Executive Committee*, Prof. Eliot R. Clark, University of Missouri, and Prof. Reuben M. Strong, University of Mississippi. Prof. C. R. Stockard, Cornell Medical School, New York City, remains secretary of the association.

Health of New York Police.—The annual report of the chief surgeon of the New York Police Department shows that the sick rate of the force for 1915 was the lowest in the history of the department, having been 21.60 per 1,000; for 1914, the rate was 22.40 per 1,000. These figures represent a saving of 5,050 days of sick leave, equivalent to 13.08 men for active performance of duty each day. During the year there were 61 deaths among the members of the force, as compared with 79 during

1914, giving a death rate of 5.06 per 1,000. The chief surgeon attributes the reduction in the sick list to the improvements made in the station houses following the sanitary inspection of all the houses in 1914, the cooperation of commanding officers in enforcing better ventilation in dormitories, and education along the lines of health extension.

Changes in the Sanitary Code.—A number of changes and additions have recently been made in the sanitary code and in the regulations of the Department of Health, among the most important being the following: Section 61, relating to water tanks on roofs of buildings, was amended to provide that every such tank shall be kept completely covered with a tight fitting cover and that every tank from which water for drinking or domestic water is furnished shall be emptied and the inside thoroughly cleansed at least once a year. Originally, this section provided that these tanks should be properly ventilated, but it was found that compliance with this provision resulted in providing openings through which mosquitoes gained access, so that the tanks were converted into breeding places. Section 128 was added to the code to regulate the sale and distribution of hair dyes and toilet preparations, since investigation had shown that the use of certain hair dyes and other toilet preparations had resulted in symptoms of poisoning, both local and general. Section 327, also a new section, which permits the slaughtering of horses and the sale of horse flesh as food, has already been mentioned.

Food and Drug Act Constitutional.—The Supreme Court of the United States on January 9 rendered a decision upholding unanimously the constitutionality of the amended food and drugs act, in the case of "Eckman's Alternative." Some years ago, in the "Dr. Johnson Cancer Cure" case, the court held that labels were "false and fraudulent" within the meaning of the act, as it then stood, only when they misstated the ingredients of the compound. In 1912 therefore, Congress passed the Sherley amendment, which provided that a shipment was misbranded "if its package or label shall bear any statement, design, or device regarding the curative or therapeutic effect of such article or substances contained therein, which is false and fraudulent." This amendment was particularly at issue in the case just decided, the containers of "Eckman's Alternative" having inclosed pamphlets in which the preparation was described as "effective as a preventive of pneumonia," with the further statement, "We know that it has cured and will cure tuberculosis." The company sending out the preparation contended that the pamphlet was not a label within the meaning of the law and that the law itself was an infringement of the police powers of the State and not properly a regulation of interstate commerce, all of which contentions were denied by the court.

Obituary Notes.—Dr. J. LEE MORRILL of New York, a graduate of the College of Physicians and Surgeons, New York, in 1869, and a member of the American Medical Association, the New York State and County Medical Societies, the New York Obstetrical Society, the Greater New York Medical Association, and the Lenore Medical and Surgical Society, died at his home, after a nervous breakdown, on January 9, aged 68 years.

Dr. LEROY DWIGHT FARNHAM of Binghamton, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1878, a member of the

American Medical Association, the Medical Society of the State of New York, the Broome County Medical Society, and the Binghamton Academy of Medicine, and consulting surgeon to the Binghamton City Hospital, died suddenly, from cerebral hemorrhage, on January 3, in Baltimore, while en route for Florida, aged 65 years.

Dr. DAVID J. HAMBURG of New York, a graduate of the College of Physicians and Surgeons, New York, in 1894, and a member of the New York State and County Medical Societies, the Harlem Medical Association, and the Alumni Association of the Lying-In Hospital, died at his home, from pneumonia, after a short illness, on January 21,

Dr. ROYAL LANGDON of Nutley, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1896, and president of the Nutley Board of Health, died at his home suddenly, from heart disease, on January 22, aged 45 years.

Dr. CHARLES STANLEY CRANE of Grand Forks, N. D., a graduate of the University of Michigan, department of medicine and surgery, Ann Arbor, in 1889, and a member of the American Medical Association, the North Dakota Medical Association, and the Grand Forks County Medical Society, died at his home, after a long illness, on December 31, aged 53 years.

Dr. WILLIAM J. TEAHAN of Holyoke, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1901, medical examiner for the third Hampden District, chief of staff at the House of Providence Hospital, and a member of the Massachusetts Medical Society and the Hampden District Medical Society, died at his home from pneumonia, after a short illness, on January 11, aged 37 years.

Dr. CHARLES HEADY BEARD of Chicago, a graduate of the medical department of the University of Louisville, Ky., in 1877, and a member of the American Medical Association, the Illinois State and Cook County Medical Societies, the American Ophthalmological Society, the Chicago Ophthalmological Society, and the Chicago Neurological Society, died at his home, on January 3, aged 60 years.

Dr. JOSIAH SWETT of New Hartford, Conn., a graduate of the University of Vermont, College of Medicine, Burlington, in 1878, for many years coroner of the towns of New Hartford and Barkhamsted, and a member of the American Medical Association and the Connecticut State and Litchfield County Medical Societies, died at his home, from pneumonia, on January 13, aged 60 years.

Dr. CHARLES M. HOLLOPETER of Portland, Ore., a graduate of the State University of Iowa, College of Homeopathic Medicine, Iowa City, in 1890, died at his home from paralysis, on December 30, aged 64 years.

Dr. JOHN H. MAXWELL, formerly of Greenville, S. C., a graduate of the Jefferson Medical College, Philadelphia, in 1854, died at the residence of his nephew in Atlanta, Ga., on December 31, aged 84 years.

Dr. JAMES C. DOUGHERTY, United States Army Transport Service, a graduate of the Baltimore University School of Medicine, in 1898, died at his home in San Francisco, Cal., on January 4.

Dr. WILLIAM BARRY BURNELL of Norwalk, Conn., a graduate of the George Washington University, department of medicine, Washington, in 1906, died at the Westport Sanatorium, on January 14, aged 34 years.

Dr. FREDERICK D. SHEPARD, a medical missionary

to Aintab, Turkey, for over thirty years, died there recently from typhoid fever. Dr. Shepard was a graduate of Cornell University and of the University of Michigan, department of medicine and surgery, Ann Arbor.

Dr. EDWIN BRIGGS WHEELER died at Philadelphia, on January 11, at the age of 64 years. He was graduated from Bellevue Hospital Medical College in the class of 1873. He was a member of the Philadelphia County Medical Society, of the Philadelphia Medicolegal Society, and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. CHARLES MONROE THOMAS died at East Goshen Township, near West Chester, Pa., on January 14, at the age of 67 years. He was graduated from Hahnemann Hospital and Medical College in the class of 1871. He was for a time demonstrator of surgery, later professor of operative surgery and of otology and ophthalmology, and for a period dean of his alma mater. He was a member of the American Institute of Homeopathy and of the Philadelphia County and Pennsylvania State Homeopathic Societies.

Dr. HENRY GENET TAYLOR died at Camden, N. J., on January 14, at the age of 79 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1860. He served as assistant surgeon in the Eighth New Jersey Volunteers during the Civil War, rendering service in twenty-five battles, and he was in later life surgeon to the Sixth Regiment of the National Guard of New Jersey. He was a member of the Camden County Medical Society and of the New Jersey State Medical Society, and a Fellow of the American Medical Association.

Dr. WILLIAM CLIFTON DREIN died at Philadelphia, on January 1, at the age of 40 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1899.

Dr. MICHAEL B. GARVER died at Ephrata, Pa., on January 3, at the age of 72 years. He was graduated from the Cleveland University of Medicine and Surgery in the class of 1871. He was a veteran of the Civil War.

Dr. RICHARD G. STRETCH died, on January 3, at the German Hospital, Philadelphia, in the sequence of an operation for appendicitis, at the age of 70 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1869.

Dr. CHARLES ZIEGLER WEBER died of pneumonia at Norristown, Pa., on January 3, at the age of 60 years. He was graduated from Jefferson Medical College in the class of 1882. He was at one time physician to the Montgomery County Prison and to the Norristown Hospital. He was a member of the Montgomery County Medical Society and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. HOWARD G. BONWILL died at Camden, N. J., on January 3, at the age of 54 years, following an operation upon his throat. He was graduated from Jefferson Medical College of Philadelphia in the class of 1886.

Dr. JAMES B. GREEN died of pneumonia at Merchantville, Pa., on January 4, at the age of 84 years. He was a graduate of the medical department of the University of Pennsylvania.

Dr. JAMES S. SPANGLER was killed at a railroad crossing at Huntingdon, Pa., on January 7, at the age of 55 years.

Correspondence.

OUR LONDON LETTER

(From Our Regular Correspondent.)

MEASLES AND GERMAN MEASLES—SUPPLY OF MEDICAL STUDENTS—ADVISORY BOARD FOR THE ARMY MEDICAL SERVICE—LORD MAYOR'S APPEAL—RED CROSS AND ORDER OF ST. JOHN SOCIETIES—OBITUARY.

LONDON, Dec. 31, 1915.

THE Local Government Board has issued an order applying a system of notification of measles and German measles throughout the country and enabling local authorities to undertake the care of patients suffering from these diseases with a view of restricting their spread, and more especially of reducing their mortality. The order with an explanatory circular and a memorandum on measles by the medical officer of the board have been posted to all local authorities, and as soon as it comes into operation cases are to be reported in the same way as now are those of other notifiable infectious diseases. Medical practitioners, parents or guardians or any one having charge of a case must report the fact to the medical officer of health at once, and the duties of these officers and the local authorities concerned are distinctly laid down. The memorandum shows that on an average about 11,000 deaths from measles occur annually in England and Wales, and besides these there are numerous deaths attributed to other causes, such as bronchitis and pneumonia, but to a large extent due to measles. Thus in the three years, 1911-13, measles caused 33,475 deaths at ages under five years, and at the same ages 83,650 by bronchitis and pneumonia—doubtless many of these were the terminal stage of an attack of measles, which is not stated in the certificate of death. It is further noteworthy that during the same three years all the notifiable diseases (smallpox, scarlet fever, enteric fever, diphtheria, puerperal fever, and erysipelas) were responsible for only 31,641 deaths at all ages, as compared with the 36,627 from measles. Measles is specially fatal in rickety children. In some outbreaks many children die from convulsions at the onset, in others pneumonia of a severe type sets in simultaneously with the fever. Other complications are chronic bronchitis, collapse of lung, dilatation of bronchi, pleurisy, empyema, pyemia, noma; these cause prolonged disablement where they are not fatal. Retarded growth, delicate condition, deafness, and other defects often follow an attack.

It is difficult to control the spread of measles, because it is infectious before a definite diagnosis can be settled. Moreover, it is so commonly regarded as only a minor complaint, which is almost a necessary one. As a cause of death it is mostly confined to young children (under five), and great care is required to prevent exposure to contagion at this age. Notification will enable segregation to be applied at an early period, which, with other measures, gives some promise of reducing the mortality.

We have been having a good deal of desultory talk about the supply of medical students, some of the papers predicting a shortage, and others starting from this point offering pictures of what would be the consequences of a diminished number of doctors. Even medical circles have talked seriously of the so-called danger, although there have long been so many complaints of over-crowding in the profession that one might rather have expected a sat-

iried tone in the anticipation of a different condition. It has been asserted that students of the first and second years, and even some more advanced, have been practically compelled by pressure of military authorities to take up combatant posts, and that such a policy is so short-sighted as to threaten grave danger both to the naval and military forces and to the civil population. It is further urged that these students should not only complete their curriculum, but that they might receive special training so that in a short time they would form a valuable reserve force to the the R. A. M. C. in case of ultimate need. It is pointed out that they might be placed in a group of men to be called up for service so late that only in the direct need would they discontinue their medical studies. Yet certain groups have been called upon which include a majority of these students, and there is a danger that instead of there being from 500 to 700 men left there may be not more than 100, and these a number under-aged and medically unfit. Not a few leading physicians and surgeons have taken up R. A. M. C. work for a time, and therefore may not discuss such questions. It is for medical councils and other officials to represent the case to the military authorities, and it is to be hoped they will not neglect to do so. The R. A. M. C. is under the supervision of the "Advisory Board for Army Medical Service," the chairman of which is the Director-General of the Department, and it includes two civilian physicians and two civilian surgeons appointed by the crown with an annual honorarium of £200. This advisory board ought to consider the question of medical students but it has held no meeting since the outbreak of the war, although one of its "regulations" is that it shall meet at fortnightly intervals and the necessary quorum for the transaction of business shall be . . . and shall report to the Secretary of State upon all matters concerned with medicine, surgery, sanitation, and epidemic diseases as they affect the military services. Though the board has not met the salaries continue to be paid and some people are asking "what for?" All questions relating to the medical organization in connection with the enormous armies in the field, whether to do with the regular R. A. M. C. staff, or civilian surgeons, all descriptions of hospitals and their supplies, whether at home or abroad, are under the control of the Director-General to whom any medical question is referred if brought before the Government. He can carry out his own views without submitting them to any other authority.

It is being asked whether any one person can do justice to himself or to the great interests involved by attempting to cope with such extensive duties. Some are very confident that he cannot and insist on the necessity of supplementing his authority by the corporate judgment of men who have time for reflection and possess the data in connection with hospitals and other institutions to enable them to meet their requirements. They hold that to induce medical students to pass to the combatant ranks is unwise and might lead to disaster. Only until the most absolute necessity demands should the scalpel be exchanged for the sword.

Responding to an appeal by the Lord Mayor several of the city companies have given sums of 100 to 500 guineas toward the Red Cross Society and the Order of St. John of Jerusalem (joint war committee). The Serbian Relief Fund has received £2,800 from New South Wales and £750 from Southport's Fund for Homeless Refugees. The em-

ployees in Devonport dockyard have sent £26 which is the sixty-fifth consecutive weekly contribution of those workmen to this fund. At a meeting of the Red Cross Society and the Order of St. John contributions to "Our Day Fund" of £800,000 were announced, of which £371,502 came from overseas. Her Majesty the Queen visited the Central Workrooms of the Red Cross Society at the Royal Academy and expressed satisfaction at the output of 10,000 garments and surgical requisites in five weeks. The Red Cross Society has been promised by the Cannock Chase Coal Owners' & Miners' Association an ambulance convoy of ten cars, costing £6000.

Dr. George Oliver, who for 35 years practised at Harrogate, has died at the age of 74. He was M. D. London and gold medallist in 1873 and Fellow of the Royal College of Physicians, where he was the Croonian lecturer in 1896 and Olive-Sharpey lecturer in 1904. He was author of "Blood and Blood-pressure" as well as of "Studies in Bloodpressure," which reached a third edition.

Dr. George Allan Heron, Consulting Physician of the Hospital for Diseases of the Chest, died on the 10th inst. He had been for some 30 years prominently associated with this and allied institutions.

LETTER FROM ALASKA.

(From Our Special Correspondent.)

CLIMATE OF NORTHERN ALASKA—NATIVE HYGIENE—EPIDEMIC OF MEASLES—A SPASMODIC CASE OF DIPHTHERIA—"A MAN OF HIS WORD."

ST. MICHAEL, ALASKA, NOV. 30, 1915.

THERE is no record of diphtheria ever having occurred at St. Michael, Alaska, before the fall of 1915. The town of St. Michael has about 150 white people, also about the same number of native Eskimos and is located on an island of the same name, which island is formed by two mouths of the Yukon river as they empty into Bering Sea. It is located at 162 west longitude and 63½ deg. north latitude.

In order to understand thoroughly what an epidemic means in such a locality as this, it is necessary to know something about these people and the conditions under which they live. The summers last about four months, during which time the snow and ice melt but the soil remains frozen about two feet below the surface. Blankets and fires are used even during these months. There are about eighteen hours of daylight out of the twenty-four and on June 22 this is truly "The Land of the Midnight Sun" with daylight during the entire twenty-four hours. Winter begins with October and lasts about eight months, the thermometer ranging from 25° above to 40° below zero. All exposed water freezes. A little snow falls every few days, and the wind, which at times assumes the character of a hurricane, blows continuously. The daylight becomes shorter and shorter until December 21, when it is necessary to light the lamps very soon after noon.

From the beginning of the freeze in October until summer, water is obtained by melting ice for drinking and for all other purposes. By November every house or shack has a large pile of ice for this purpose. Building material is extremely scarce here; there is not a tree within 200 miles, and the soil or tundra is probably of glacial origin, rolling in contour, frozen in winter and a huge swamp in summer. As a result of these conditions the native lives in small shacks (made as nearly air-tight as he can make them) with very low ceilings, one or two

small windows, and a storm door entrance. He dresses in fur boots or muclucs, fur gloves, such clothing for trousers or coat as he can get, and over all a parka made of fur which covers the head as well as the body. These fur goods are made of local furs, usually reindeer, and are tanned by the native. The tanning is crude and a part of the process is accomplished by rubbing the skin with urine. Some of the sewing is done with fibrous tissue which has been soaked in the mouth until pliable. As would be expected, these finished products have a very strong and disagreeable odor, even in cold weather. To add another aroma to the person and surroundings the natives eat and rub themselves with seal oil which has been collected possibly many months before and kept standing in an open vessel around the house. However, the principal component of their diet is dried salmon and their persons and shacks always have a strong and disagreeable odor of this. These fish are caught in summer, stripped, and hung up in the sun to dry, then covered with seal oil and tied up in bundles of convenient size in which form they are sold to the natives and stored in their houses. They sometimes cook these, but usually eat them raw.

Water is scarce and the native rarely bathes. Heat is expensive and hard to get so there is usually one room in the house and the entire family lives in that, covering themselves with poorly tanned furs or dirty blankets and closing every possible opening through which the wind could come. Bearing in mind the above, it is not surprising that tuberculosis is very common among the Eskimo and that an epidemic spreads like wild-fire among them. Their resistance is low and there seems to be little or no immunity to disease among the natives of this section of Alaska, as they contract readily and in a large percentage all communicable disease to which they are exposed.

In 1900 an epidemic of measles occurred in the native village at St. Michael and it is said that fully one-half of the native population died of it; in some instances whole families were found dead in their shacks. This epidemic was stopped after a most vigorous quarantine was established, segregating the sick, exposed, and those who had not been exposed. The native as a rule does not believe in medicine and has his own medicine man who treats him by "medicine songs" and other such methods. As they are uneducated and superstitious an effective quarantine is difficult. However, a few, and especially the "squaw men" (white men who have married native women) and sometimes their families, do believe in medicine to a certain extent.

On October 12, 1915, a "squaw man" came to me and said "I have been spitting up chunks of something from my throat." On examination a grayish membrane was seen covering his right tonsil, pillars, right side of the uvula, and adjacent parts of the hard palate and pharynx. Smears were made immediately and the Klebs-Loeffler bacillus found in them, this being afterward proved by cultures. The man was given 3,000 units of antitoxin subcutaneously before leaving the room. We repaired to the native school house and got his only child, a boy of ten years, took him to his house, and gave the child 500 units and the wife 500 units of antitoxin as an immunizing dose. Cultures were made from the throats of the child and wife, the former were negative and the latter positive for the bacillus of diphtheria. These people live in a native shack about twenty-five yards from the nearest building.

The writer realized the importance of an effective quarantine and the question "How can this be done?" at once arose. The entire island is under the control of military authorities and such civilian authority as exists is subordinate thereto. The civilian authorities consist of a U. S. deputy marshal, probate judge, and a jailer who handle only trivial cases, and the question of a quarantine had never been put up to them before, so it required some time to determine whether or not they could manage the case. In the meantime, the commanding officer of the military was asked to put a guard over the house to prevent any one leaving or entering it. This he immediately did. The weather was very cold and the wind blowing hard; everything that could freeze was frozen, even the sea five miles out from shore. The deputy marshal finally found a provision of the law by which he could serve a notice on this patient whereby he might be imprisoned sixty days and fined \$50 if he broke his quarantine. The guard was removed, notice served, and a sign "Diphtheria" was placed on the house.

This man is a Laplander by birth, fifty years of age, and has lived in Alaska for more than twenty years. He married an Eskimo fifteen years ago and has lived in St. Michael ever since. He was very indignant when the soldier was placed over his house and asked to have him removed saying, "I give you my word of honor that no one will leave or enter this house until you say so." As the notice was not read to him, he did not realize what its contents were and neither the deputy marshal nor the writer knew that the patient did not understand. However, after being in quarantine ten days he became familiar with the true nature of the legal paper and at once became very indignant, making various threats even against the deputy marshal for having doubted his word. This was smoothed over by telling him that it was required by law to serve the notice. A close watch was kept on this house and a survey made of the village daily, but no new cases developed.

It may seem strange how this case was contracted! And here is the explanation. St. Michael is the terminus of the Yukon river boats on which many tourists and others come from and go to the various river points and Southeastern Alaska, a distance of over 2,000 miles. At this place they have to wait from a few days to several weeks until an ocean vessel arrives from Nome en route to Seattle or San Francisco. On October 7 and 8, this squaw man was intimately thrown with the passengers and the crew of one of these vessels. Three days after the sailing of the ship he was taken sick and there is every reason to believe that he contracted diphtheria from a carrier among the passengers or crew, and the quarantine officer at Seattle, Wash., was so notified by wire. This marks the first case of diphtheria reported from this part of Alaska and it is felt that a great victory was gained in taking this man as "a man of his word" and not antagonizing ignorant suspicious people.

Tracheal Casts in Diphtheria.—W. Fedorovsky states that expulsion of a membranous cast of the trachea after tracheotomy through the tube is not infrequent, but spontaneous expulsion through the mouth is rare. He reports a fatal case in a soldier, age 29 years, secondary to typhoid fever, and has collected 7 other cases from the literature, 2 in adults, ages 19 and 33, the rest in children, ages from 4 to 11.—*British Journal of Children's Diseases*.

1. Gunshot Fractures of the Extremities.—Robert B. Greenough, Robert B. Osgood, and Beth Vincent state that during a three months' service, from April 1 to July 1, 1915, in the University Service of the American Ambulance, at Neuilly-sur-Seine, France, 132 patients, or about one-third of the total number of admissions, presented one or more fractures of the extremities. In 16 cases more than one of the long bones was broken, so that data on 148 fractures are available for study. There were 129 compound fractures and 19 closed, or simple fractures. Of the 129 compound fractures 8 were incomplete, and the bone was merely grazed or grooved by the bullet, without solution of continuity or abnormal mobility. Among the complications sepsis was the most to be feared. Infections from gas-producing organisms were not unusual. Secondary hemorrhage was not an unusual complication of gun-shot fractures. Where sepsis continued for a long time bone fragments became devitalized and were sequestered. Delayed union and non-union were complications to be feared. Following long fixation of joints and lack of use, it was to be expected that many cases of ankylosis and contracture would occur. In summarizing they state that early and thorough operative treatment is indicated in gun-shot fractures received under the conditions of trench warfare; that the removal of missiles, foreign bodies, and detached bone fragments, and thorough drainage are important; that complete immobilization in extension is as a rule best obtained in a base hospital by plaster dressings, put on under an anesthetic; that frequent and painstaking dressings, with or without irrigation, and the maintenance of free drainage are of great importance in overcoming sepsis; that prophylaxis is better than corrective treatment in the avoidance of ankylosis of joints, and contractures of muscles and tendons.

2. Simulation of Esophageal Stenosis by Extensive Carcinosis of the Lesser Curvature of the Stomach.—A. Everett Austin says that, in a classical description of a typical esophageal stenosis, the symptoms are always described with such accuracy that it would appear that there would be no difficulty in diagnosing such a form of disease. Experience has taught that there are forms of carcinosis of the stomach which are not so clearly defined as those of which the classic symptoms have been given; in other words, they lie upon the border line between these two forms, and often require a great deal of ingenuity in order to differentiate them. The deglutition sounds, in his hands, have proven very unsatisfactory. In one case reported special reference was made to the difficulty of deglutition, apparently one of the earlier symptoms. No blood was produced by the introduction of a tube against the growth. A residue, shown by the x-ray examination, twenty-four hours after the ingestion of bismuth is extremely rare. The question may arise whether one is really within the stomach itself, or is in a pouch. The answer to this question can usually be determined by the presence of rennin which is, of course, a feature of gastric secre-

tion, and usually persists in the cancerous stomach, long after the hydrochloric acid is eliminated. A second case he reports had two noticeable peculiarities, the short duration and the apparent absence of great emaciation. He concludes that the actual cause of the obstruction in these two cases is not due to cardiospasm, nor to true malignant stenosis, but is due to an edema which occurs wherever there is a widespread carcinosis of the lesser curvature, which approaches the cardia. As in a long continued dysphagia, existing in one instance under his observation for twenty years, the conclusion must be that it is not malignant, but is due to spasmodic constriction or to a diverticulum.

3. **A Note on the Simulation of Diabetes Mellitus.**—George Blumer says that simulation of diabetes mellitus is probably not of very frequent occurrence and hence he reports in detail a case that came under his observation. The simulation of the disease may take three forms: (1) addition to the urine of sucrose; (2) the addition to the urine of glucose; and (3) the production of an artificial glycosuria by the consumption of phloridzin or phloroglucin. Simulation of diabetes mellitus is easier than that of many other diseases because of the lack of objective physical phenomena in mild and uncomplicated cases, and because the urine in such cases presents no characteristic chemical abnormalities aside from the presence of sugar. The detection of sucrosuria is simple if certain precautions in the care of the urine are observed. Failure to observe these is what has led to failure to detect the imposture.

1. **Increasing Mortality in the United States.**—Eugene Lyman Fisk has made a study of the mortality statistics of the registration area of the United States and, as Director of Hygiene of the Life Extension Institute, has examined large numbers of people throughout the country. He states that the widespread premature physical decay, which is suggested by our vital statistics, is to a considerable degree confirmed by actual examination of large groups of supposedly healthy young people. Thousands of people are slowly and inevitably preparing for physical breakdown or premature death and there can be no more important work for modern medicine than to bring such cases as early as possible under proper hygienic or medical guidance. There is probably some particular influence at work causing the upward trend in mortality from organic diseases. This may be found in our rapid industrial and social evolution, bringing about a condition of widespread prosperity and lavish expenditure, which relatively extends to the comparatively small wage earner. A natural adjustment to these conditions may ultimately come about, but we cannot rely upon this vague prospect and should bend our energies to the utilization of all the resources of science to check this rising death rate in middle life. To this end the lines that offer promise are eugenics, periodical physical examination for the purpose of detecting physical impairment, which may suggest important modifications of occupation or living habits, and the application of principles of personal hygiene.

2. **The Facial and Trifacial Nerves.**—Samuel Horton

Brown reports the case of a man, who, during a routine examination of the refraction for the relief of asthenopia, mentioned that he was subject to profuse lacrymation and blinking every time he chewed. A careful examination to determine the cause of this condition showed that there was no inflammation except the slight chronic catarrhal condition so frequently seen in patients when they present themselves for a change of lenses. The entire lachrymal apparatus appeared to be normal. The facial expression seemed to be normal, but inspection on several occasions showed that the left lower lid was not so tonic as the right. This case history is offered as a possible explanation of some of the associated jaw and lid reflex. The epiphora is taken to be the result of the physical condition caused by the drawing down of the facial tissues when the lower jaw is moved. It is questionable if there is any reflex in this case, except that which follows after the eye is exposed by drawing the lid away from the globe.

3. **Diet in Chronic Heart Disease.**—Robert Abrahams says that in the management of chronic heart disease it is essential, first and foremost, to ascertain to what extent the heart is in difficulty, and to what degree its action is embarrassed. A patient with mitral or aortic disease, enjoying good compensation, need fear nothing except overindulgence in any diet. A patient with valvular disease and partial broken compensation may with impunity partake of any diet, but, instead of taking three big meals a day, it is better that he takes six small ones. The diet of a patient afflicted with valvular lesions and complete loss of compensation, must be in the main liquid, and his feeding hours frequent. The same applies to the victims of myocardial degeneration. Valvular lesions minus myocarditis, differ from myocarditis in relation to diet. Valvular disease alone has periods of perfect compensation and no venous stasis, while chronic myocarditis always has imperfect compensation, hence the ever-present congestion and the necessary caution in the selection of food. A gouty heart emphatically forbids the use of meat. Cardiac disease associated with chronic kidney trouble requires a diet more adapted to the renal condition than to the defective heart. A lesion of the heart which is preceded or followed by arteriosclerosis puts a veto on a proteid diet. Sufferers from chronic heart disease should scrupulously avoid overeating and should be cautioned against the use of copious drafts of water, particularly at meals.

6. **Spinal Anesthesia with Stovaine.**—J. Sturdivant Read has used spinal anesthesia with stovaine in a series of fifty cases of genitourinary surgery. The solution used is that devised by Babcock, stovaine 0.08, lactic acid, 0.002, alcohol 0.2, and distilled water 1.8. For urological operations the third or second lumbar interspace is selected, as complete anesthesia is secured and the danger of depressing the cardiac and respiratory centers is considerably increased when injections are made in the higher spaces. This particular preparation has a lighter specific gravity than the spinal fluid, consequently the needle having been quickly withdrawn, the patient is laid flat on the table and the head and shoulders are lowered to prevent blocking of the upper nerve roots, and sometimes interference with the respiratory and cardiac centers. In this series of fifty cases no symptoms of severe cardiac or respiratory depression occurred. The rapidity with which anesthesia may be obtained by this method and the small degree of post-operative shock and discomfort make this the method of choice in many cases. In cases of phthisis, or other pneumonic involvement, and in the presence of kidneys which are damaged or not functioning freely, it is of great advantage.

1. Vesiculotomy and Vesiculectomy.—Louis E. Schmidt discusses the indications for the different operations, the symptomatology of seminal vesiculitis, the classification of cases, the methods of procedure, and the anatomy and surgery of the vesicles, and describes the technique of operative interference that has given the greatest degree of success in his hands. He believes that if a patient has an involvement of one or both vesicles which does not result in a spontaneous cure, he should receive a surgical consideration. The most essential point in the technique of operation is that the patient should be placed in the extreme lithotomy, position, as this permits of accurate incisions into the vesicles or their removal under direct observation. The patient should also be immobilized. The skin incision should be either the semi-lunar or the inverted V-incision, practically extending from tuberosity to tuberosity. Other incisions may be made provided good access can be attained. The median tendon should be exposed and divided. With blunt dissection the fossa either side should be opened and then the urethrectal muscle divided. This then permits of exposure of the prostate and vesicles which are hidden by the fascia of Dénouvillier. The writer has practically always found that when this procedure was followed surgical interference to the vesicles could be carried out. There were additional devices that might be resorted to, however, for bringing the floor of the bladder with the vesicles covered with fascia into view.

2. Signs of Death.—Thomas F. Reilly says there are a few single symptoms pathognomonic of death, but a combination of two or more symptoms will often lead us to make a positive statement as to its approach. It is well never to give an absolutely fatal prognosis in typhoid fever or cholera so long as there is life left in the body. Except in heart block a pulse under 80 in an adult means that death in any event is probably at least more than twelve hours off. This is not true of the aged. In old persons a pulse of 140 means death within a few hours at most. Even in coma a pulse of 100 usually means that death is at least eight or ten hours off. Cases of auricular flutter are very deceptive; those with gallop rhythm, not associated with rheumatic carditis, are always fatal. A very high blood pressure, say 230, which suddenly falls below 100 without signs of hemorrhage usually indicates a fatal issue. Cheynes-Stokes phenomenon, excepting in auricular fibrillation, is always a fatal sign. A marked disproportion in length of inspiration and expiration is suggestive of danger. In any disease the presentiment of a fatal issue by the patient at the onset is a bad omen.

Coma is the commonest form of death, about 60 per cent. of patients die in coma. The author considers the significance of eye signs and other signs, such as the facies, hematogenous jaundice following fever, loss of sphincter control, persistent and uncontrollable hic-cough, loss of more than half the body weight, convulsions lasting four days, disappearance of peripheral reflexes, and edema of the glottis in patients over 45 years of age. With a lowered blood pressure, accompanied by increased rapidity of the heart followed by marked tympanities and the appearances of profound shock; these signs followed by irregular pulse, delirium, restlessness and hallucinations, and later by stupor and coma invariably presage death. Less often one sees another form of death in acute disease. The patient is cyanotic, there is great dyspnea, the jugulars are full and pulsating, often there is marked pulsation over the right heart. The heart dulness is increased to the right and the lower dulness increases downward. Rarely is such a patient saved.

3. Resuscitation by Means of Preserved Living Erythrocytes in Experimental Illuminating Gas Asphyxia.—W. H. Burmeister reviews the theories with reference to the causes of death in carbon monoxide poisoning and describes his attempts at resuscitation in rabbits and dogs by means of transfusion with erythrocytes preserved from three to seventeen days. He concludes that the erythrocytes of some animals can be preserved intact over extended periods of time. These corpuscles can again assume their physiological function in another animal of the same species, and can successfully prevent death in carbon monoxide, asphyxiation of this second animal, in about 75 per cent. of all cases in which direct infusion is begun while cardiac contractions can still be elicited. The establishment of emergency stations where human erythrocytes could be obtained, just as pulmotor stations were now being maintained, should prove of invaluable service in saving human beings who were the victims of illuminating gas asphyxiation.

4. Food Poisoning by B. Paratyphosus B.—Harry S. Bernstein and Ezra S. Fish describe an epidemic of food poisoning which occurred at Westerly, R. I., characterized by symptoms of acute gastroenteritis, in which it is estimated that sixty persons were made seriously ill and four died. All of those who were ill traced their symptoms to pie eaten at a restaurant. Bacteriological and feeding experiments demonstrated the presence of *B. paratyphosus* B in specimens of the pie. The presence of the organisms in the pie could not be accounted for; the theory advanced that a carrier was responsible could not be proven, as the personnel of the restaurant had not undergone any change in several months and these cases all occurred within a few hours from the time the patients had eaten of one particular batch of pies. This occurrence points to the possibility that even cooked or baked foods may contain living pathogenic organisms and emphasizes the necessity of protecting public food supplies more carefully from "disease carriers."

14. A Direct Route for Drainage of the Pancreatic Area.—Walter D. Wise reports a case of acute pancreatitis, diagnosed as appendicitis, in which the McBurney incision was made. The appendix not being at fault, a high right rectus incision determined the diagnosis. Drainage was provided through the foramen of Winslow also through the McBurney incision. The lower incision was chiefly depended on for the drainage, as it could be seen that this line was very direct, the pancreas being exposed by lifting the great omentum and transverse colon. The writer recommends this procedure for conditions of the pancreas demanding drainage.

1. **The Treatment of Dysentery.**—Ronald Ross writes this article because medical men in England have not had the opportunity of collecting experiences in the treatment of amebic dysentery as have those in warm climates. He relates the history of the treatment of dysentery in the past and the methods used at the present time and calls attention to the fact that the large number of troops come from Britain, Australia, and New Zealand and are therefore men who have never had amebic dysentery before. Many of the cases are at first exceedingly grave, as grave in fact as any that the writer has seen among European troops freshly arrived in India. Many of them die before reaching the base hospital, and those that survive have frequently reached the condition of "running dysentery," which always suggests that a large proportion of the mucosa is already destroyed. On the other hand, it was remarkable that among the Indian troops who are exposed to amebic dysentery from childhood there was not nearly the frequency of severe cases. The method of treatment that they are using is the administration of one grain doses of emetine hydrochloride daily, given either in one subcutaneous injection or in two doses morning and evening. In one hospital the method of three days on and three days off was used and in another five days on and five days off. In India emetine was frequently given daily not only for weeks but even for months. Sulphates of sodium and magnesium also played an invaluable part in the treatment of amebic dysentery. The author also calls attention to a means of diagnosing dysenteric ulcerations with the x-ray which was worked out by Lieutenant Glasson in one of the Alexandrian hospitals.

2. **Penetrative Wounds of the Abdomen.**—W. B. C. Meyer and D. C. Taylor and Anthony Bowlby publish the results obtained by laparotomy for penetrative wounds of the abdomen in the first 50 cases operated upon at the 17th Casualty Clearing Station near Flanders. They have also observed 41 cases which were not operated upon, 17 because they were beyond help and the remaining 24 because it was not necessary. All of the latter recovered. This fact they state demonstrated that selection is justifiable. In 34 out of the 50 cases operated upon the intestines or stomach were wounded. Twenty-one of these patients recovered in spite of multiple perforations in many cases and serious injury to other viscera. Resection appears at first sight to be much more fatal than suture, but it must be remembered that the wounds that necessitated resection were also much more severe and the patients far more ill. The essentials for success in operations upon gunshot wounds of the abdomen were briefly as follows: 1. Rapid transport to hospital. 2. Suitable aseptic and antiseptic conditions for operation. 3. Good nursing and suitable feeding. 4. Opportunity for retaining the

patient for at least a week or ten days before evacuation. In a note added by Sir Anthony Bowlby he says that it has been his advice that all wounds without exception be subjected to an exploratory operation, and that a laparotomy should be done if the peritoneum is found to be involved. Operation should also be done in all those wounds of the gluteal and lumbar regions where the symptoms point to a visceral lesion. He does not advise operation in the epigastric or hepatic region, especially in antero-posterior wounds if there are no definite symptoms. The same holds good of the renal and splenic regions.

4. **Widal's Reaction with Agglutinable Cultures.**—E. W. Ainsley Walker states that since the early summer of 1915 standardized agglutinable cultures of *B. typhosus*, *B. paratyphosus* (A), and *B. paratyphosus* (B), and standard agglutinating serums for these microorganisms have been made widely available by the Medical Research Committee on whose behalf they are issued (with directions for use and diagnostic data). For the individual worker these preparations offer the advantage that they are always ready, there is no making of cultures in advance or preparing emulsions, and they are absolutely sterile and require no expert knowledge in handling. The readings are quite clear and definite and are quickly made. The standardized agglutinable cultures are highly sensitive to agglutination, and they can be kept unchanged for a year or longer. The employment of an accurate quantitative method of carrying out agglutination tests possesses special value in the diagnosis of the presence or absence of active typhoid or paratyphoid infection in typhoid inoculated persons.

1. **On the General Treatment of Infected "Gunshot Wounds" from a Clinical Point of View.**—H. M. W. Gray says that since the war began they have been compelled to acknowledge the inefficiency of antiseptics in badly infected lacerated wounds. He points out the disadvantages of the hypochlorite treatment of infected wounds and states that the saline treatment of septic wounds has stood the test of time. As the claims of the saline treatment have been urged chiefly by laboratory workers the writer, in July, 1915, sent out a list of questions to twenty-two hospitals in the vicinity of Rouen for the purpose of collecting evidence as to the clinical results of this treatment. From the replies it seems that the general opinion is that the hypertonic treatment is so satisfactory that it is unnecessary to add antiseptics and that the treatment may be discontinued when the wound is clean and covered with granulations. The answers brought out clearly that the method of application must vary with the type and situation of the wound, with the condition of the wound, and the length of time since it was inflicted. The baths were most popular and were practically always used in wounds of distal parts of the extremities. Continuous irrigation was mostly used after flapless amputations; simple soaks were used for lacerated shal-

low wounds, especially when they had begun to clean. Tablet and gauze packs were judged to be best for deep and fairly recent wounds, and drainage tubes were recommended for long tracks and recesses. An extraordinary variety of opinion was expressed with reference to the amount of pain occasioned by the saline treatment. It was brought out that warming the dressings, as with a hot water bottle, greatly increases the lymph flow. The majority of the replies brought out the fact that hydrogen peroxide was used, but mainly for its mechanical effect in loosening dressings.

2. Vaccine Treatment of Chronic Bacillary Dysentery.—Leonard Rogers reports 11 cases of bacillary dysentery treated with sensitized vaccines. In none of them was there anything beyond a moderate degree of reaction at the seat of the injection, while there was never any increase of the bowel symptoms or other toxic signs for a single day. The sensitization appeared therefore to have fulfilled the expectation which led the author to employ it. Considering that the majority of the patients were sent from various parts of India, after the failure of prolonged treatment of different kinds, and that the doses used were always small, probably much less than might be used with advantage in patients resisting the treatment, the results might be considered as affording good ground for hoping that, with further experience, this line of treatment would prove to be an important advance in dealing with intractable cases of chronic bacillary dysentery. Sensitized vaccines also appeared worthy of cautious trial in quite small doses, but with shorter intervals, even in the more acute stages of the disease.

6. Traumatic Implantation of Epidermis in Tract of Gunshot Wound.—G. H. Edington reports this case and says that theoretically there is no reason why the carrying in of one or more fragments of living epidermis should not occur in a certain percentage of gunshot wounds. This case presented certain features not usually seen in the cases occurring in civil life. It appears that in civil life such implantation followed by the formation of a "dermoid" is usually the result of a trifling injury. It would also be expected that the thicker the epidermis the greater would be the likelihood of its being carried into the deeper tissues. This condition occurs in the palmer surfaces of the hands and fingers and there is no part of the body more subject to trifling injuries and at the same time more likely to be the seat of "implantation dermoids." It is therefore interesting to note the occurrence of implantation in this case in which the part struck was the back, where the epidermis is much thinner than in the palm, and the injury was by no means trifling or unheeded.

Functional Tests of the Heart.—Rehfish states that the present war gives us new cardiac affections. The older literature of soldier's heart is very meager, and the author finds but one monograph on the subject, to wit, Da Costa's "Irritable Heart" (1871) which deals with the troops in the American Civil War. The author now has notes of 800 cases of heart troubles in soldiers, and would emphasize that we have not a single test to discriminate between an efficient and inefficient heart. Three separate components are present, the myocardium, vascular system, and innervation. The author first gives the auscultatory criteria of a sound heart. The "ten genuflexions" test sends extra venous blood into the right heart and if the latter is healthy it readily adapts itself to this excess and propels it at once through the pulmonary circulation to the left

heart, and so on. The second aortic sound should still be louder than the second pulmonary. But if the left ventricle is inefficient, it gives somewhat, the blood pressure is lowered and the accentuation of the second aortic sound is less marked. In hundreds of cases—70% of all tested—Katzenstein's method of compressing both femoral arteries has brought out an insufficiency of the left ventricle, as shown by a fall of blood pressure and a weakening of the second aortic sound. The insufficiency of the right heart is determined according to the same principles, but is a more serious condition and means actual disease of the myocardium. The author as a result of repeated autopsies on soldiers has learned that in over 43% of subjects between 20 and 30 arteriosclerosis was present, with especial reference to the aorta and left coronary. This condition is clearly acquired as a result of military hardships.

A Year's Treatment of Pneumonia with Ethylhydrocuprein.—Silbergleit has treated forty-nine cases of pneumonia with this alleged chemotherapeutic remedy and lost five of them (10.2%). Before this period he had treated forty-five consecutive cases without this medicament and had lost four or ten per cent. In the latter series all of the decedents had been interned on the first day of the disease, which was not the case with the ethylhydrocuprein series, only one of the five decedents having been interned the first day, the others all arriving late or about the time the crisis was due. These figures show a slight advantage in favor of the new remedy. In regard to the date of defervescence there was likewise an advantage, but it is safe to say that this quinine derivative has no specific power over pneumonia which is at all comparable with that of quinine over malaria. The number of complications in the series of forty-nine was but one (empyema), with one relapse. There was also an impression in the mind of the medical attendant that the patient was not so very ill. The influence of the new remedy may be compared with that exerted by a good antipyretic, which keeps down the fever and its attendant ills without injury to the patient. The drug is no cardiac roborant, despite the finds of others. It has a bad taste and sometimes causes nausea and tinnitus severe enough to demand the suspension of the treatment. There was a single case of amaurosis. The author believes the remedy a desirable one if it can be begun on the first day of the disease.

Gas Gangrene and the Rauschbrand of Sheep.—Steinbrück, a veterinary, sees a close connection if not a possible identity between a certain affection which attacks sheep, goats, and swine and the gas gangrene of wounded soldiers. The term Rausch as here employed indicates the peculiar crackling or crepitus obtained on passing the fingers over the affected area, and which has always been regarded as present in all spreading gangrene as a result of the formation of gases of putrefaction. The Rausch brand occurs in particular geographical areas and is not contagious. After a very brief incubation period swelling appears about the throat, jaws, and shoulders or perhaps on the limbs. These lesions appear, at least in many cases, to represent metastases from a primary focus. Fever does not develop. The animals refuse food and perish as a rule in from 12 to 40 hours. The swellings, at first warm and painful, soon become cold and insensitive. Autopsy shows that the muscles are permeated with a gas which gives off the odor of butyric acid. The affected parts are also saturated with hemorrhagic serum, and the latter is

present in the large serous cavities. From lesions visible in the liver, it seems probable that small, dry foci, of ocher color and honey-comb texture, as large as a pea or bean, are characteristic of the malady. The cause of the latter is known—an anaerobe bacillus of definite characteristics. It enters the skin or mucous membrane, preferably if a pocket-like defect is present, and as a rule in the gums during the change of dentition. It is unfortunate that war conditions make it impossible to investigate satisfactorily the relationship between the animal and human diseases.

Inspid Diabetes and the Hypophysis.—Hoppe-Seyler states that much remains to be cleared up concerning our knowledge of diabetes insipidus. It has been seriously regarded as a hydromania—an insane desire to drink water with resulting polyuria; but this affection should be termed a polydipsia such as may accompany various psychoses. Genuine diabetes insipidus is first of all a polyuria, which calls for water to replace the loss; if this is not forthcoming the body fluids tend to dry up and a uremic condition is the result. In this form of diabetes symptoms point to an intracranial mischief, originating about the region of the fourth ventricle. Various mechanical results as wounds, tumors, etc., in this vicinity can bring about insipid diabetes. In regard to the hypophysis the disease in question appears to be a deficiency symptom, and injections of hypophysis extract have power over the polyuria. The author recently had under his charge a typical case of insipid diabetes. There were no symptoms which pointed to intracranial mischief. Under hypophysis extract a notable improvement appeared in the urine without the ill consequences. On stopping the extract the urine again became copious and of very low density and the intensity of the polyuria caused rapid loss of weight. The return to the extract again caused a reversal of symptoms. Given by the mouth no improvement resulted. The extract is able to hold the disease in check, but no cure follows. An x-ray showed a normal sella turcica, and the cause of the polyuria could only be reached if at all by exclusion. Several suspicious factors were present, such as increased tension of the cerebrospinal fluid.

Military Surgical Experiences to Date.—Matti concludes an article on this subject, having outlined an account of the leading methods tested in both Germany and Allied armies. He is committed to some form of antiseptics. As a dependable application under various circumstances he recommends iodine tincture 10 per cent. in alcohol. A leading indication is superficial wounds. Here the iodine combines with the tissue albumins and incidentally, through its oxidizing power destroys the anaerobes. In large, deep wounds there is present the danger of iodine intoxication. Nevertheless it is a known preventive of tetanus infection, and from its power over anaerobes in general is indicated with precautions. Peroxide of hydrogen has lost none of its good repute as a war antiseptic, and is especially indicated for irrigation of irregular wounds. In putrid wounds, phlegmons, infected joints, etc., carbolic acid solutions—from ½ per cent. up—are recommended, while another old standby, Balsam of Peru, is still in favor. Iodoform and camphor are regarded more as cell proliferants than antiseptics and are added to iodine at times. In discharging wounds where wet dressings are in order, boric acid and salicylic acid solutions give good results. But chemical antiseptics cannot

be carried out until mechanical and physical antiseptics have first been employed.

Treatment of Meningitis with Silver Preparations.—Wolff calls renewed attention to the close resemblance to the meningococcus and gonococcus, the latter being sensitive toward silver salts. The gonococcus, even in rare instances, can cause spinal meningitis. *In vitro* the meningococcus is equally vulnerable to silver, and recently weak protargol solutions have been injected into the spinal cord in cases of meningitis, and the author, using a most elaborate technique, has sought to perfect this method of treatment. Much pains were taken to prevent pain and irritation and other drawbacks. The therapeutic injection was preceded by lumbar analgesia, which was designed to prevent irritation by the silver and was not always successful. In any case the irritative effects of the silver were not prohibitive, and the salt appeared to diffuse rapidly through the cerebrospinal fluid. The patients, who of course were suffering from meningitis, found the injections burdensome, but this counted for little in so deadly a disease. There were two possibilities, viz.: death of the meningococci and arrest of its proliferation. The author treated in all five cases of a disease of which the normal mortality is from thirty to 70 per cent., and in all cases ended in recovery. Four cases were of medium severity and one of extreme gravity. Apparently no serum was given. The author's theory was as follows: epidemic cerebrospinal meningitis is above all a local infection. In this respect it is radically different from certain hematogenous forms (tuberculous, pneumococcal). The germ reaches the cerebrospinal fluid by means of the lymphatic connections between the nasopharynx and the meningeal sac. Only in very rare exceptions do we find cocci in the blood (meningococcus sepsis) with secondary implication of the meninges. The use of protargol in this connection is based solely upon the analogy of the gonococcus with the meningococcus, so that it is not impossible that a better bactericide may be discovered in time.

Rickets a Deficiency Disease.—H. L. Watson-Wemyss says the following facts speak in favor of the theory that rachitis is due to a lack of vitamins in the child's diet: (1) Rickets is less frequent and milder in breast-fed children; healthy breast milk always contains vitamins. (2) Breast feeding has a favorable effect on rickety children. (3) The nourishment of nursing women is often totally inadequate, and this may lead to deficiency of vitamins in their milk. (4) During the winter months the food supply of cows is often inferior, this leading to an inferior quality of milk. (5) The harmful effect produced on the vitamins of milk by prolonged boiling. (6) The harmful results of feeding children with starchy foods, which are poor in vitamins. (7) The beneficial effect of cod-liver oil, which contains vitamins, and also apparently a substance which aids the metabolism of lime salts in rickety children.—*Edinburgh Medical Journal*.

Horny Growth on Arm.—W. Knowsley Sibley reports the case of a healthy married woman, aged 60, who presented on the anterior surface of the left arm just above the bend of the elbow a horny growth, which measured 1½ inches in length and was slightly curved, pointed and shaped like a bird's beak. It was hard and horny in consistence, and dark brown to black in color, but had a fleshy base, and was stated to have commenced some six months ago as a moist wart to which the patient had applied caustic. It was growing entirely upon the soft tissue and was not situated over a bony surface, as is usually the case with such growths.—*Proceedings of the Royal Society of Medicine*.

OXFORD WAR SERIES. NERVE INJURIES AND SHOCK. By WILFRED HARRIS, M.D. (Cantab.), F.R.C.P. (London), Physician to St. Mary's Hospital, London, and to the Hospital for Epilepsy and Paralysis, Maida Vale, Capt. R.A.M.C. (I.), 3d London General Hospital.

SURGERY OF THE HEAD. By J. BATTIE RAWLING, M.B., B.C. (Cantab.), F.R.C.S. (Eng.), Surgeon and Senior Demonstrator of Operative Surgery, St. Bartholomew's Hospital; Major R.A.M.C. (T.F.).

ABDOMINAL INJURIES. By RUTHERFORD MORISON, Professor of Surgery, Durham University; Senior Surgeon Northumberland War Hospital; and W. G. RICHARDSON, M.B., F.R.C.S., Lt.-Col. R.A.M.C., 1st Northern General Hospital and Surgeon Royal Victoria Infirmary, Newcastle-on-Tyne.

GUNSHOT INJURIES OF BONES. By ERNEST W. HEY GROVES, M.D., M.S. (London), F.R.C.S. (Eng.); Surgeon to the Bristol General Hospital, Consulting Surgeon to the Cossham Hospital; Capt. R.A.M.C. (I.).

INJURIES OF JOINTS. By ROBERT JONES, Ch.M., F.R.C.S. (E. and I.); Director of Military Orthopedic Hospital, Liverpool; Consulting Surgeon to Queen Mary's Convalescent Auxiliary Hospital (T.F.), Major R.A.M.C.

WOUNDS OF THE THORAX IN WAR. By J. KEOGH MURPHY, M.C. (Cantab.), F.R.C.S.; Surgeon to the Miller General Hospital for Southeast London; Surgeon to Paddington Green Children's Hospital Staff Surgeon, R.U.V.R. Late of H.M. Hospital Ship *Soudan* No. 1.

MEDICAL HINTS FOR THE USE OF MEDICAL OFFICERS TEMPORARILY EMPLOYED WITH TROOPS. By J. EDWARD SQUIRE, M.D. (Lond.), F.R.C.P., D.P.H. (Camb.); Companion of the Order of the Bath; Knight of Grace of the Order of St. John of Jerusalem; Lt.-Col. (Hon. Col.) late R.A.M.C. (V.); Consulting Physician Mount Vernon Hospital for Diseases of the Chest, etc.

SANITATION IN WAR. By Major P. S. LELEAN, F.R.C.S., D.P.H., R.A.M.C., Asst. Professor of Hygiene Royal Army Medical College, with an introduction by Surgeon General Sir ALFRED KEOGH, K.C.B., M.D., F.R.C.P. With 39 illustrations.

INJURIES OF THE EYES, NOSE, THROAT, AND EARS. By ANDREW MAITLAND RAMSAY, M.D., F.R.F.P.S. (Glasgow); Ophthalmic Surgeon, Royal Infirmary (Glasgow), Major R.A.M.C. (T.P.); J. DUNDAS GRANT, M.D., F.R.C.S. (Eng.); Late Major R.A.M.C. (Post-office Volunteers), King George Hospital, London; Lord Kuntzford's Special Hospital for Officers; H. LAWSON WHALE, M.D. (Camb.), F.R.C.S. (Eng.); Capt. R.A.M.C. (T.P.), formerly No. 13 General Hospital, British Expeditionary Force Overseas; The County of London War Hospital, Epsom; and CHARLES ERNEST WEST, F.R.C.S. (Eng.); Aural Surgeon to and Lecturer in Aural Surgery at St. Bartholomew's Hospital; Capt. R.A.M.C. (T.P.). Price of each volume in the series, \$1.00. London: Henry Rowde, Oxford University Press; Hodder and Stoughton; New York: The Oxford University Press, American Branch, 1915.

THESE remarkably handy little volumes, known as Oxford War Primers, are of course, an outcome of the war. The present war has not only closely engaged the attention of surgeons from the fact that an immense number of men have been and are being seriously injured but also because many new problems in surgery have been presented.

The books in the series under notice have been compiled by specialists who in the numerous campaigns now being undertaken, are rendered capable of speaking with the authority of recent experience.

Not all the volumes, however, deal with the surgical aspects of war; one is devoted to the situation from a medical angle, and one is given up to a consideration of perhaps the most important problem of any, that of sanitation in war. It would be invidious where all are excellent to select one or some for especial commendation. The volume on sanitation in war will possibly prove of the greatest interest to the general practitioner. It is pointed out that antityphoid inoculation has conclusively proven its value and the British Government is somewhat sharply criticised for not making

that precautionary measure compulsory in the army and navy. The rôle of insects in war, and especially of flies, is discussed in an interesting manner. The medical hints are extremely good and cannot but prove most useful to the hundreds of British practitioners who have left the quiet paths of private practice for the more eventful career of military surgery.

Very valuable advice is given by Morison and Richardson with regard to the treatment of abdominal injuries. An outstanding feature of the casualties in the present war is the very large number of cases of nervous exhaustion and functional paralyses of various kinds, which are being met with as the result of shell explosions, etc. This subject is adequately dealt with. The series will undoubtedly be largely read by English speaking practitioners with much benefit to themselves. They should prove useful to officers of the Medical Reserve Corps in this country.

THE TREATMENT OF GONORRHEA AND ITS COMPLICATIONS IN MEN AND WOMEN. For the General Practitioner. By WILLIAM J. ROBINSON, M.D., Chief of the Department of Genito-Urinary Diseases and Dermatology, Bronx Hospital and Dispensary; Editor, *The American Journal of Urology, Venereal and Sexual Diseases*; Editor of *The Critic and Guide*; Author of *Treatment of Sexual Impotence and Other Sexual Disorders in Men and Women*; *Sexual Problems of To-day*; *Never Told Tales*; *Practical Eugenics*, etc. President of the American Society of Medical Sociology; Ex-president of the Berlin Anglo-American Medical Society; Fellow of the New York Academy of Medicine; Member of American Medical Editors' Association; American Medical Association; New York State Medical Society; Internationale Gesellschaft für Sexualforschung; American Urological Association, etc. Price, \$2.50. New York: Critic and Guide Company, 1915.

THIS volume is written by a genitourinary specialist with the two-fold purpose of providing a serviceable work for the general practitioner and of stating his own methods and ideas on the subject of gonorrhea and its complications. The book differs from most other works of the kind in that it does not represent, except incidentally, the views of other writers. The author has produced a book which is unusually readable and which will form a serviceable addition to the works on genitourinary diseases in the library of any practitioner. We do not like the word "urethritides" as used by the author (on pages 18 and 19) for various forms of urethritis; urethritis is the correct form. Two chapters are of more than ordinary interest and value. One of these is the chapter on "Prevention of gonorrhea," which contains information not to be found in most of the text books. "Vulvovaginitis in little girls" is also discussed in a separate chapter, and treats of a quite common affection in an admirable manner; this, too, is a topic either entirely ignored or most inadequately handled by most of our writers. The last forty pages of the book are taken up with a brief discussion of the various remedies, antiseptics, anesthetics, lubricants, etc., used in genitourinary work; these chapters form a fitting conclusion to a work of real merit. We note an omission on the title page; the author neglected to inform his readers that he was a member of the Medical Society of the County of New York. This was probably covered by the "etc.," but in the interests of completeness it should have been stated.

THE INTERVERTEBRAL FORAMINA IN MAN. The Morphology of the Intervertebral Foramina in Man, including a description of their Contents and Adjacent Parts with Special Reference to the Nervous Structures. (Supplement to "The Intervertebral Foramen"), by HAROLD SWANBERG, Member American Association for the Advancement of Science. With an Introductory note by Prof. HARRIS E. SANTEE. From the Anatomical Laboratory, Chicago College of Medicine and Surgery. Illustrated by eleven original full-page plates. Price, \$1.75. Chicago: Chicago Scientific Publishing Co., 1915.

THE author's valuable anatomical studies on the intervertebral foramina of the lower animals is supplemented in this volume which describes the intervertebral foramina in the human being. There is presented a detailed description of these structures and of their contents and immediately adjacent parts. This monograph, the original of which appeared in an article by the author in the *MEDICAL RECORD*, is an important contribution to the science of anatomy. It is of particular interest to those who have studied the therapeutic possibilities of spinal manipulation.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held December 16, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Otology.

Orientation and Equilibrium: A Study on the Sense of Position and Movement; Dependence on the Vestibular Apparatus and Importance in the Whole Field of Medicine.—Dr. ALFRED B. DOLL presented this communication. After referring to the vast amount of literature that had accumulated with reference to our knowledge of position in space and adjustment to it, he spoke briefly of the work of Flourens, in 1828, who first demonstrated that the semicircular canals were definitely connected with the movements of the head; of Schrader's experiments on frogs, and of Professor Lee's experiments on sharks, which hardly left any doubt as to the participation of the semicircular canals and the labyrinth in the equilibration process. These and other physiologists had given added proof that the vestibular apparatus was a special sense organ, solely concerned with orientation and equilibration, and that its physiological connection with the auditory apparatus was practically nothing compared with its intimate connection with other special senses, such as sight, the kinesthetic sense (muscle-joint), and the sense of touch. Hence the main object of this paper was to bring out this fact which was not generally appreciated, namely, that the eighth nerve, the auditory, should be described in anatomy and physiology as the nerve of hearing only, with its end organ, the cochlea, the so-called vestibular branch should be given a place by itself, and should be described as the nerve of orientation only, with its end organ, the vestibule, and the semicircular canals. So far as the anatomical evidence in the matter was concerned it might be observed that the distribution of the vestibular and auditory fibers was to entirely different centers. One had but to contemplate for a few moments the various precise poises of the body in space, together with the adjustments of the limbs and other parts to the accurate localization required in daily existence, to be deeply impressed with the nicety of the mechanism which controlled them. The development of these adjustments to meet the demands of increasing activities was very rapid. A normal child of seven or eight years had unconsciously acquired a sense of orientation, by an adjustment of muscles and joints, which in magnitude far exceeded that acquired in later years by practice and training for the most difficult pursuits. This particular function of orientation was more important than any other in the struggle for existence. Its evolution might be traced from the stiffened tentacle of the jelly-fish, through the calcareous particles of the higher forms to the more elaborate vestibular apparatus of the vertebrates in which it became most important in all the acts of the individual. As the higher order of beings was reached the sense of position was safeguarded and augmented by intimate association with other sensations, sight, the kinesthetic sense, hearing, touch, smell, etc. In the perfectly normal individual the conception of position was the result of the harmonious assembling of all these afferent impulses. Loss or imperfect action of any of them produced a disharmony which if not corrected resulted in a misconception varying to the degree of the upset. There might be simply a slight uneasiness or uncertainty at the mere thought of some daring act of equilibration, or some previous experience, like looking from a dizzy height, a rough sea voyage, a ride on a merry-go-round, or other psychic illusory idea. Again, there might be a varying degree of vertigo resulting from the actual experiences, the thought of which might cause the psychic vertigo, and on to the more violent manifestations of vertigo accompanied by nausea, vomiting, loss of equilibrium, and ataxia. Through all this one should not lose sight of the fact that the vestibular apparatus was the most essential factor in the sense of orientation, the only source of such afferent impulses as had to do with that sense alone. The phylla deprived of its stiffened tentacle, the higher forms deprived of their otoliths, completely lost their sense of position and could not maintain existence. In the human, in whom the struggle for existence was the fiercest, it was quite natural that the compensatory factors for the loss of this sense of position furnished by the vestibular apparatus should be more complex. A man deprived of one vestibular

apparatus was temporarily greatly upset in his sense of position; as a result he had violent vertigo, which his other senses made frantic efforts to correct. The violent effort to correct a change of position which was not actual, resulted in loss of equilibrium. These efforts to compensate for the loss of a vestibular apparatus succeeded with varying rapidity. The more violent manifestations subsided in a few days, and in a few weeks the ordinary acts were performed with apparent ease. However, in such a case the orientation could not be said to have become perfect again, but the individual had simply adjusted himself to the loss. Perfect orientation required angulation; impressions must come from the two different vestibular apparatuses at the same time, and the individual had learned the trick of moving his head or eye to get a point of view from two slightly different angles at practically the same instant. The deaf mute born without vestibular apparatus, did many acts of equilibration with perfect ease and might miss many of the upsets of life which those with perfect orientation might have. He might never experience the throes of *mal de mer*. The loss of both static labyrinths was a great catastrophe. While the first symptoms might not be violent, the task of learning to orient without the aid of organs specially designed for it was much like a blind person learning to read from the sense of touch, of the deaf one interpreting the movements of the lips from the sense of sight, and often the results were quite imperfect.

To appreciate this one had only to try any of the more difficult acts of equilibration on such a patient. For instance, he might be asked to try to stand on one leg, with the eyes closed, to walk forward or backward with the eyes closed, or an act of walking or turning in the dark. The normal individual might have the illusion when sitting in a train at a station that the train was moving, when, in reality, it was a train by his side that was coming in or going out of the station. This optical illusion was quickly corrected by the normal individual by looking at some upright portion of his own car which was not moving, or by closing his eyes, when the optical illusion was corrected by the static labyrinth. If a congenital deafmute were to have this illusion it would have to be corrected by the sense of sight. If he closed his eyes the illusion would remain, particularly if there were no vibration which would upset his tactile sense. The essayist stated that in having introduced this subject in a somewhat desultory manner he hoped he had succeeded in showing how orientation might be upset by misinformation from many sources; how impulses from the static labyrinth were so powerful to correct the misinformation, and, on the other hand, how misinformation from the static labyrinth itself was corrected with comparatively great difficulty by other afferent impulses. He would leave it to those who followed to point out the methods of fixing the cause of disequilibrium on peripheral or central organs; on functional or organic disturbance; on lesions of the different afferent sources of information; the cerebellum, or the cerebrum, which after all must be the source of our consciousness or position as well as that from which we voluntarily changed it.

Dr. F. H. PIKE confessed to a certain hesitancy in speaking of anything so apparently well known as the otic labyrinth to such an audience. The subject was so well known that the man in the street immediately associated the otic labyrinth and the cerebellum with the maintenance of equilibrium. So firmly was the belief that the cerebellum was the great central mechanism for the maintenance of equilibrium fixed in the mind that there was a strong tendency in some quarters to assert that the disturbance following lesions of the labyrinth and lesions of the cerebellum were essentially similar. If one was to distinguish between these lesions it was more important to point out certain constant differences in the effects rather than to dwell so strongly upon the resemblances. The difficulty of limiting the effects of a pathological lesion to the area primarily involved was rather great. One might have first the effects of pressure resulting from intracranial growth and also the increased secretion of cerebrospinal fluid which usually accompanied an intracranial tumor. In the case of intracranial or mastoid abscesses there was the spread of toxins and other effects upon remote parts of the nervous system, and there was the difficulty of getting human material for post-mortem examination at the time when such examination was most desirable for the pathologist. It seemed to the speaker that their clinical observations should be supplemented by experimental work, since by the experimental method one

could avoid the effects of intracranial pressure and bacterial toxins upon other parts of the nervous system, and one could control both the primary and the associated experimental lesions within certain limits. Dr. Pike showed lantern slides illustrating the effects of a lesion of the labyrinth and of the cerebellum upon a considerable number of animals. These figures, for the most part, had been published in the Philosophical Transactions of the Royal Society of London, 1912, Series B, Vol. 203, pp. 127, and in the Supplement to the Transactions of the American Otological Society, 1914, Vol. XIII, part II, by Prof. J. Gordon Wilson, and himself. In all the animals so far studied the effects of experimental lesions of the labyrinth resulted in torsion of the head to the injured side. Immediately after the operation the animal might turn and roll over to the injured side. When both labyrinths were removed at once, the animal might refuse to stand unassisted, but would lie with the limbs and head as close to the floor as it could get them. The animal learned to stand after a few days, and to walk about without falling. But even for months afterwards it would be unable to jump even from a moderate height without falling in a heap. This observation was originally due to Schiff and they had repeated it many times. There were always certain deficiencies of this kind which might be discovered by careful examination of animals from which the otic labyrinth had been removed. Looking at the nervous system from the point of view of its evolution, it was seen that in the lower forms of vertebrates the cerebral hemispheres formed a very inconsiderable portion of the whole nervous system. But as successively higher animals were taken it was found that the anterior end of the nervous axis, that was the cerebrum, showed a greater and greater degree of development. Experimental findings agreed very closely with the anatomical development, and all the facts so far gathered pointed to the increased importance of the cerebrum in the daily life of the animal. On the basis of the anatomical development and of a considerable number of experimental facts, it was his belief that one must look more and more to the cerebrum as the great central mechanism for orientation in space rather than to the cerebellum.

Dr. ARNOLD KNAPP spoke of the rôle of the eyes in equilibrium and orientation. Among the nervous impulses which acted in preserving equilibrium, those obtained from the eyes were mentioned as important and, according to Gowers, the knowledge of the relation of external objects to the body gained from the contraction of the muscles of the eyeball was one of the most important sources of guidance to the centers that regulated the muscular contractions for maintaining bodily equilibrium. There was a close association between the eyes and the labyrinth but not directly connected with equilibration; it had a different purpose, as shown in the following: The posterior longitudinal muscle which connected the various nuclei of the ocular muscles was in close relationship with the vestibular nerve. This nerve, thereby, was closely associated with the ocular muscles, just as it was with all the muscles of the body. It served the purpose of maintaining the muscles in a state of tonic contraction. If this nerve was divided on one side, it would result in a complete loss of tone of the muscles of the body of the opposite side and in nystagmus. The vestibular apparatus was also in close relationship with the cerebellum, by means of Deiter's nucleus, so that the cerebellum was a further factor in the regulation of their ocular movements. Bing called it a reflex apparatus serving for the preservation of equilibrium, not only for the muscles of the body, but for the eyes. It received centripetal impulses from the static labyrinth and from the ocular muscles by means of Deiter's nucleus, which assisted in its regulating activity. On the other hand, it sent forth centrifugal impulses through this same nucleus which preserved the position of equilibrium and control of the ocular movements. In certain animals the position of the eyes and their movements were governed nearly exclusively by the ear. The eyes in these animals, if the head was not moved, were practically motionless. As the head moved, the eyes made a compensatory movement in the opposite direction, which originated in the labyrinth. There was a constant action of the labyrinth on the ocular muscles. It held the ocular muscles in check, gave them a definite tone, so that a lesion of one labyrinth caused a preponderance of the action of the opposite side. In man this association between the eyes and the labyrinth also worked for producing compensatory

movements, though these were not as important as in the lower animals. The purposes of these compensatory movements, according to Sherrington, were presumably for maintaining the normal relation of the eyes to the horizontal. These movements, Wilson and Pike had shown, were a direct reflex response, independent of the cerebellum, to insure that the retinal images should not be disturbed by each motion of the head. It was well known that if both labyrinths were destroyed, these compensatory movements were abolished. The chief symptom, so far as the eyes were concerned, which resulted from a lesion of the labyrinth, was nystagmus; this, however, was a symptom which did not disturb their sense of equilibrium. In other words, those suffering from nystagmus did not complain of vertigo unless there were other agencies which affected the center of equilibrium. Ocular vertigo was a very unusual symptom and was difficult to explain. Vertigo occurred, unquestionably, in ocular paralysis, owing to the confusion resulting from false projection; this, however, was a symptom which was surprisingly frequently absent. Muscular anomalies, such as insufficiencies of the ocular muscles, were practically never accountable for vertigo. The term dizziness, as used by patients, embraced many conditions and symptoms which had but little to do with vertigo; it was often impossible to analyze these symptoms or to explain their relation to an ocular defect, particularly when other factors which cause vertigo could not be excluded.

Dr. J. RAMSEY HUNT discussed the importance of the vestibular mechanism in neurology and said that the otic labyrinth was of great importance neurologically as it was the terminal end organ of an extensive sensory mechanism which had connections with many portions of the central nervous system. This mechanism was frequently involved in affections of the nervous system, organic, functional and psychic, and when the seat of pathological disturbances produced symptoms which were essentially neurological in character a knowledge of the functions and relations of the vestibular nerve was essential to a proper understanding of vertigo, equilibrium and orientation, nystagmus, and cerebellar localization. The otic labyrinth might be regarded as a highly specialized end organ of the vestibular division of the eighth cranial nerve. Dr. Hunt roughly represented the course and termination of this nerve which was, so to speak, the anatomical basis of vertigo. It was bilateral mechanism and for its proper function a strictly harmonious action was required from each side simultaneously. If by reason of irritation or paralysis of the end organ on one side only, an asymmetrical stimulation resulted with the production of true labyrinthine vertigo. The nystagmus of vestibular origin was rhythmic in character and consisted of two components, a slow movement followed by a rapid return movement. The direction of the nystagmus always referred to the direction of the rapid movement. It was always more manifest when the eyes were turned in the direction of the rapid nystagmus; it was diminished or suppressed in the direction of the slower component. Vertigo might result from labyrinthine disturbances, disease or injury of the vestibular nerve in the internal auditory canal and at the base of the brain, and affections of the central nervous system, more especially of the brain stem and cerebellum. Organic brain disease was one of the most important and most frequent causes of vertigo. In regard to the treatment of labyrinthine vertigo, Dr. Hunt said he wished to emphasize the good results which had occasionally been obtained by lumbar puncture.

Dr. LEWIS F. FRISSELL said that the rôle of the general practitioner in discussing the subject of vertigo, especially after listening to the brilliant expositions from the special points of view of aurist, physiologist, ophthalmologist, and neurologist, was a trifle difficult. Why was he here at all? The answer seemed to be that as ancient Rome gave her successful general a triumph with captives at his chariot wheels, so our first consul had consented to accentuate the papers of the evening by insisting on the violent contrast of an internist discussing the specialist's pet field. The general man was, however, deeply concerned in that to his inexperienced hand came the patient seeking relief from real symptoms, and here came both his perplexity and his duty—to which branch of the dazzling array of specialists should the patient be referred? Was it a case of labyrinthine vertigo and was the aurist to be called upon, or was muscular weakness of the eye the predominant factor? Was it a cerebellar tumor or a disease of the central nervous system which demanded the special

attention of the neurologist? Or, more difficult still, was it one of those threshold cases on the borderland of epilepsy simulating labyrinthine disease, so admirably described by Gowers? Fortunately, the dissensions of the internal groups somewhat helped the perplexed practitioner. Ménière's original description of auditory vertigo was of a symptom complex, of sudden vertigo associated with nausea, vomiting, and deafness on the affected side; in other words, a disease showing the same symptoms as our experimental animals in which the semicircular canals of one side had been extirpated, the reasons for which had been so admirably described by his predecessors. But gradually it was found that all cases did not have either the classical symptoms of Ménière's disease, or the classical cause—destruction of the labyrinth, but varied in intensity from slight tinnitus with vertigo to the severe type originally described. So arose the classification into Ménière's disease and pseudo-Ménière's, the former having as its pathological base the destruction of the labyrinth, while the latter was attributed to slighter forms of disease such as otitis media, changes in pressure of the endolymph, cerumen in the external meatus, disturbances in the vestibular nerve in its course to the central nuclei, or even more remotely to tabetic changes and the functional explosive irritation of the higher centers in the epileptic aura and attack. But if vertigo might be attributed to so many diverse sources in which the ear was affected directly or indirectly, what of those cases in which muscular incoordination in the eye produced diplopia and a false and uncorrected concept in the brain, the vertigo of multiple sclerosis—that psychic type caused by looking down from a height in one unaccustomed to mountaineering; the common incoordination of acute alcoholism, and that distressing form met with in "mal de mer"? Must the general practitioner be relegated to the undignified position of "Mother Sill" and be altogether eliminated from the diagnosis and treatment of this common malady? In its ultimate analysis, the causes of these symptoms constituted in many, if not in most cases, a distinctly medical affliction, as syphilis, arteriosclerosis, aortic insufficiency, the various types of anemias, diseases of the gastrointestinal tract, which were directly responsible not only for the appearance of the symptoms, but in many cases for the pathological base of the symptom complex, the latter forming only a localizing symptom of a constitutional disease. One must conceive it to be the duty, then, of the general practitioner in the presence of vertigo, by careful examination of his patient, including particularly blood, urine, blood pressure, and serological examinations, first to determine the presence or absence of underlying constitutional disease; and secondly, by careful examination of the eye, ear, and nervous system to determine in which special field the immediate defect causing vertigo lay. If, as was probably the case, he was himself unable to apply the more complicated rotation and caloric tests in the ear or make a thorough examination for muscular strain or defective vision in the eye, he should refer such a case to the better trained specialist for a more thorough examination. But with his broader field of vision, he should be able to coordinate the examinations of his technically more skilled confrères and would often be enabled to arrive at a more correct diagnosis in a difficult case. In treatment, too, where a cure might not be obtained by a correction of muscle palsy, a regulation of pressure in the labyrinth or by operative procedure, his handling of the hypertensive and anemic conditions might greatly improve, or in syphilis brilliantly cure, the underlying conditions. Therefore, the internist's plea was that even in this field he might be allowed some slight recognition from his more skilled brethren and might be able to retain his place in the care of so obscure and puzzling a condition.

Dr. A. JACOBI wished to make a contribution from his own experience, for digestion by the specialists. He himself was subject to one particular kind of vertigo which he always experienced whenever he was on the second story of a building looking out of a window for just a few seconds. There was very little vertigo in his head, but a great deal in his feet and legs; they began to tingle, and the feeling crept up over the knees. A little cerebral vertigo was connected with the sensation. He would be very glad to have this explained, and explained soon, for he was believed to be an old man and would like to be able to understand it soon. All his life he had been perfectly healthy, so far as he knew; he had had no brain disease, no tuberculosis, no syphilis, but just fifty years ago he had typhus. It might be

that he had something in his brain that gave him this peculiar vertigo or unsteadiness when he looked out of a window. He would like to know what it meant, for nothing of the kind had been mentioned this evening, and it might be that in this only respect he was quite unique. He was sure he had it when he was thirty-five years of age. He did not remember having experienced it before his typhus, but he had had it ever since.

Dr. JOSEPH BYRNE said that distinction should be made between equilibrium and orientation. Equilibrium was a means of orientation, but must not be considered as the equivalent of orientation. Orientation in general might be said to be the *perception* of one's relations to the environment. An old definition of truth was that it was conformity between thought and thing. Orientation might be defined as conformity between the immediate testimony of our senses and our relations in space and our conception of what those relations were or ought to be. They had, then, in orientation two fundamental elements, viz., (1) the immediate testimony of our senses, and (2) our conception, based on education and experience, of what our relations in space under any given set of circumstances ought to be. It was evident that the second element was mainly psychological and formed the background for the interpretation and evaluation of the first element, i.e. of present incoming sensory impulses from all sources. In so far as element number one was in accord with element number two in so far as we were oriented. Conflict to a certain degree between these elements caused disorientation, i.e. uncertainty of one's relations with consequent sense of insecurity, fear, etc. The labyrinth was no more the organ of orientation than many other sensory mechanisms, e.g. kinesthetic, visuocular, tactual, etc., which informed us immediately of the actual relations of our bodies in space. But information from these sources had to be interpreted and evaluated against the background of experience before they entered into the mechanism of orientation. Absence of element number two did not cause disorientation, but simply absence of orientation, or ignorance of one's relations in space, that was like a child before it had learned through the different senses its relations in space. The importance of element number two would be apparent from the consideration of a few examples. When a person with eyes closed, seated upright in a swing, feet off the ground was rotated about the long axis of the trunk in the direction of the hands of a watch, there was a primary horizontal nystagmus in the direction in which the subject was actually moving. If the swing be allowed to slow down gradually there would come a time when the nystagmus became reversed (secondary nystagmus) i.e. horizontal against the hands of the watch. At this moment, if the eyes be kept closed and the feet off the ground, the subject would believe his body had reversed its direction and was now turning against the watch, i.e. in the opposite direction to that in which it might be actually turning. If the feet were put on the ground the eyes still being closed, the subject at once was disillusioned. The conditions of this experiment were so unusual that there was little or no background against which to interpret the incoming sensory impressions. The only experience the normal individual had of impressions from violent horizontal nystagmus was that associated with active turning of his body about the long axis. In the experiment, this *plus* the impressions from the nystagmus constituted element number two and the testimony of all the remaining senses under the circumstances offered no conflict, hence there was no disorientation, but merely an illusion. One more example: An individual, absorbed in thought, standing on a ferry boat before the latter was loosed from its moorings, allowed his eyes to rest on the water streaming past. Presently he believed his boat was moving. Here the background consisted largely of a state of expectation that his boat was about to move and the testimony of the senses, so long as his eyes saw only the moving water, offering no conflict, an illusion was begotten, namely, that the boat was moving. A new psychological background was then formed, based on the illusory motion of the boat. Now when the eyes turned from the moving water and rested on stationary objects, the testimony of the senses, element number one, came into conflict, not with the testimony of the other senses as so many authors claimed, but with element number two, which at that moment was a false conception, namely, that the boat was moving. A revulsion of feeling followed coupled with uncertainty and insecurity which was called disorientation. Examples might be multiplied

indefinitely, but enough had been said to show that the psychological element or background was a fundamental factor in orientation and that disorientation did not consist in conflict between the immediate testimony of the senses, but between the latter and number two, or the background derived from education and experience.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Seventy-fourth Meeting, Held Friday, Dec. 3, 1915.

DR. JOHN S. THACHER, PRESIDING.

Extensive Keloid of Face after Treatment.—Dr. ROBERT ABBE showed this patient. The young man had been presented two years before to the Society. His face had been badly burned with acids, causing loss of one eye and immense keloid formation, as hard as leather covered wood, all over the face. The keloids had been largely removed by radium applications. The case was so much improved that it had reached a point where plastic repair could be done by the surgeon and the nostrils and eyelid could be improved. This case had taken a long time and very slow and careful work was necessary in such a condition.

Nevus of the Face.—Dr. ABBE also presented a case of nevus of the face in a child, who on account of the extensive cavernous type of the lesion had not been weaned until it was two years old. There had been nevoid degeneration in the throat, causing the child great difficulty in swallowing and giving a croupy cough. By thorough application of radium the outside nevus had been obliterated and the great purple mass had been reduced to the normal color of the skin. With the disappearance of the external development the nevoid growth in the throat had yielded. The child who had choked all the time had recovered its voice and was enabled to swallow perfectly. Attention should be called to the healthy color of the skin. The application consisted of 25 mg. of radium, once a week, for half an hour. This treatment had extended over two or three months.

A third case presented was one of nevus on a girl's face, the recent photograph of which showed an almost normal condition. Dr. Abbe added that in cases of spontaneous keloids between the breasts in girls, and such a case as was shown, where a girl had been scalded by burning soup, radium caused disappearance and levelling of the masses. The photograph showed the condition.

Dr. THACHER asked how many applications had been used in the case of the child. In regard to the other case he asked if the picture was taken by the lumiere process. He asked if the treatment of hemorrhages from fibroids with radium was successful and also if the action of radium produced an obliterative endarteritis.

Dr. JAMES asked what could be the cause of keloids on the chest. He wanted to know if certain people were not predisposed to keloids. He said he had seen negroes with keloid formation wherever a scar had occurred. He thought they were predisposed. One man developed a keloid wherever he had been cut.

Dr. THACHER said negroes were predisposed to keloids.

Dr. A. A. SMITH asked how often it was desirable to apply radium, and if the treatment was attended with any pain.

Dr. JAMES asked if malignancy could develop through the action of radium, as with that of the x-ray.

Dr. PARK said he understood it would have the reverse effect.

Dr. PECK asked if radium was successful in the case of larger fibromata.

Dr. KNAPP said he remembered a case of angioma of the orbit in a child, which produced exophthalmos. Dr. Abbe had kindly suggested making an incision in the upper lid and inserting a radium tube which was left in the orbit for half an hour. This was done nine months ago. The tumor at present was very much reduced in size and there was now practically no exophthalmos. The cutaneous (nevus) condition had, of course, not changed.

Dr. THACHER asked if it had been used for intracranial angioma.

Dr. ABBE said he had not seen anyone with that condition.

Dr. M. A. STARR said it had failed in a case of glioma.

Dr. ABBE said in reply to Dr. Starr that they had had to make many trials and some failures had occurred. To Dr. James he said that the causes of keloids on the chest were various. He had five cases. In one a dermatologist had used the electric needle. In one a keloid had followed pricking a pimple. A true keloid was usually made worse by surgery. He said he had views upon the question of predisposition to keloids, which he had not had time to work out. He thought that probably in those cases it was not so much idiosyncrasy as infection. To Dr. Thacher he said the treatment of hemorrhage from fibroids was one of the advances of modern surgery. The overgrown myomatous tissue was absorbed after the use of radium. The radium produced a retrograde action of the tissues and it was now not necessary to use the knife in the treatment of myomata. To Dr. Smith he answered that the treatment was used once or twice and it was attended with no pain whatever. To Dr. James and Dr. Park he said that malignancy could not develop. The action of the radium ray was quite different from that of the x-ray. It caused an atrophic condition. To Dr. Peck he said that in regard to the larger fibromata he had treated one, one foot in diameter. The hemorrhages were entirely stopped and the patient was now in perfect health.

Myxoma of the Lung.—Dr. J. C. ROPER presented a man of fifty-three years, an Austrian, a carpenter by trade, who was admitted to the New York Hospital, Sept. 27, 1915, complaining of pain in the chest and cough. The family history was negative. No previous illness was noted. He was moderately alcoholic and used much tobacco. Four years ago a painless swelling appeared on the lower part of the left calf. This had remained practically unchanged and was not troublesome except for an occasional slight stabbing pain. His present complaint was of pain in the chest, dyspnoea and much cough with profuse expectoration. These had developed five months before admission and had persisted with slight variation. His bowels were constipated. The pain was augmented with deep breathing. On admission the white cell count was 48,000; polynuclear cells, 90 per cent. The Wassermann was negative. On physical examination in addition to the tumor of the calf, referred to above, a small tumor was found in the left popliteal space. There was distinct enlargement of the glands at the left femoral ring, one being estimated as 3×1.2 cm. The left chest gave signs over the lower portion of fluid, or new growth. The pain was referred to the upper abdomen, but x-ray bismuth pictures failed to show any lesion in the intestinal tract. The tumor was then removed from the leg and proved to be a myxoma. The chest was aspirated on several occasions and a small amount of tissue was obtained, the appearance of which justified an attempt to obtain a better specimen. A puncture was then done with a large needle and considerable suction. A specimen of tissue showing the structure of a myxoma was obtained. Myxomatous tumors of the viscera were very uncommon. Dr. Roper said it had been quite interesting to be able to make the diagnosis during life. The question had been raised as to whether the tumor was in the pleura or the lung. This could not be definitely decided, but the x-ray plates suggested the lung as the probable site.

Dr. THACHER said the case was most unusual. He asked if it was purely myxomatous; if there were any sarcomatous elements or any signs of fluid. He said these tumors tended to develop into sarcomata.

Dr. ABBE asked if there was any weakness of the ribs. Did Dr. Roper think that the tumor was metastatic? He said he had had a case of the same type. In his patient, a young man of fine build, the tumor had appeared on the back, between the shoulder blades. The patient had had twelve operations in one year. The growth recurred. He had gone to the Mayo Clinic but they could do nothing. Finally, he came back to Dr. Abbe and Dr. Coley. Dr. Coley used toxins and Dr. Abbe used radium. The tumor was now beginning to shrink. Whether the improvement would be permanent he could not say. There was serious involvement of the intercostal muscles and pleura, and perhaps the lung itself. There was no known remedy for such a serious condition.

Dr. ROPER said in answer to the questions of Drs. Thacher and Abbe, that sections showed no evidence of sarcoma, although mixed tumors were common, as far as observed these particular tumors were purely myxomatous. There was no involvement of the ribs.

This type of tumor did not tend to form metastases, but did tend to recur locally if not completely removed. As the tissue of these tumors was so preeminently of an embryonic character, it was probable that the different tumors developed from preëxisting embryonic deposits, rather than from metastases.

The Tobacco Habit.—Dr. ROBERT ABBE read this paper (see page 177).

Dr. GILMAN THOMPSON said that he had been interested lately in the biographies of centenarians and there were a large number of smokers among them. He was interested to hear Dr. Abbe state that cigarettes were less harmful than other forms of tobacco. That had not been his experience. Among cases of the so-called "tobacco fiends" he had seen a predominance of cigarette smokers. The cigarette smoker took a number of smokes all through the day. The cigar smoker generally took his smoke after meals or exclusively in the evening, but the cigarette smoker did not confine the habit to post-prandial indulgence and was more constantly under the influence of tobacco. In cigarettes also one got paper smoke, and cigarette smokers suffered much from bronchial irritation and chronic pharyngitis and laryngitis. Another point that Dr. Abbe had not touched upon was the possible effect, in so-called chronic smokers, of tobacco on arterial pressure. He had had the impression that if a man smoked a great deal it would raise his blood pressure. Dr. Thompson took this up with his Chief of Clinic, Dr. W. H. Sheldon, who had made observations on over sixty patients who were smokers. The patients sat in a small closed room where they smoked cigars for an hour or two. The blood pressure was taken before and after. The results averaged nearly even on either side of the normal arterial pressure. In some the blood pressure fell about 10 mm. In some it was raised in a like degree. In a few cases the blood pressure rose 15 to 20 mm. The results seemed to depend on temperament and habit. In neurotic patients there was a slight elevation. Phlegmatic workmen, used to smoking a clay pipe, would have a slight fall in pressure, following the soothing effect of the smoke. Dr. Sheldon was going to publish the results in tabulated form. The personal equation entered largely into this question. Some persons ought never to smoke and some persons were not injured in the least by the habit. It depended on the mode of use and also on the constitution of the smoker. The habit was certainly unnecessary as the world got along very well without it for very many centuries.

Dr. GORHAM BACON said he saw many cases of chronic catarrhal deafness which were undoubtedly made worse by excessive smoking. He always advised these patients to smoke very moderately. Noises in the ears were often caused by excessive smoking. One man who went on a "tobacco debauch" would come to him to have his ears blown out and was advised to cut down his tobacco, and he always improved when he smoked less. Dr. Bacon said that if he smoked too much himself his ears began to ring.

Dr. VIRGIL P. GIBNEY said he had had no practical experience in this subject, but it had been a matter of common observation with him for a number of years that periodic alcoholics had smoked cigarettes most intemperately just prior to an outbreak.

Dr. WALTER P. JAMES said there seemed to be very little accurate scientific knowledge of tobacco and its effects. He confessed that he had not considered that the paper in cigarettes had anything to do with irritation. He supposed burning paper smoke was just burning cellulose, different only from tobacco smoke in that the latter contained nicotine. He thought the injury from cigarette smoking came from smoking all the time and on an empty stomach. Many smoked in bed and started again the first thing in the morning. If smoked in moderation cigarettes should be less harmful than other forms of tobacco. Dr. James said he thought a good many men could smoke Porto Rico or domestic cigars who could not smoke the strong Cuban cigar. He knew of one man who could get along comfortably smoking domestic cigars until some kind friend sent him Havanna cigars, which he could not resist, and he immediately suffered from the poisonous effect. Dr. James had noticed another point and wondered if any of the clinicians present had noted it. This was that a sensitiveness to tobacco often came on at the age of 50 or 55 in some smokers. Suddenly they found tobacco disagreed and they complained to the tobacco dealer that their old brand of cigars was deteriorating. In some people this sensitiveness seemed almost like

anaphylaxis. They felt depressed and got a bad taste after smoking. Some had to stop entirely. Another point was that if a man smoked right along and then stopped smoking for 3 or 4 months and then began again, he suffered from sensitiveness. In another way tobacco seemed to be an unusual drug. A boy suffered very much from his first smoke, or a man might vomit from the effect of his first cigar, but after that he could smoke without feeling it. What other drug was there that gave such a marked effect the first time and then no effect at all later?

Dr. JOHN W. BRANNAN said that he thought that the first part of Dr. James' statement was true, but he was not sure as to the latter part.

Dr. CLEVELAND said that at ten years of age he was ill for twenty-four hours from the effect of a cheap cigar. He did not smoke again until he went to college.

Dr. M. ALLEN STARR said that in two nervous diseases it had been demonstrated that the use of tobacco greatly affected the patient. One was the ordinary hereditary tremor which passed from generation to generation. This often began about forty-five years of age, with a fine tremor of the hands and perhaps of the head. He had watched four families through three generations, with this disease. One patient said the tremor so much increased by using tobacco that he could not write or sign a check after smoking. He, however, always took his cigar. Patients suffering from melancholia were always distinctly worse after tobacco. He had always advised these patients to stop smoking. In painful nervous affections, each as neuritis and locomotor ataxia, the pain was sure to be increased by smoking.

Dr. THACHER asked Dr. Starr if there were any of these individuals who found tobacco soothing.

Dr. STARR said that tremors and pains were not soothed by it.

Dr. PARK asked if the irritative effects of tobacco had any rôle in producing pulmonary effects. Was there ever a sort of immunity gained by smoking?

Dr. GILMAN THOMPSON said that tobacco smoking helped to break up some types of asthmatic attacks, just as did strong coffee.

Dr. PARK asked if any relation had been traced between tobacco users and pneumonia.

Dr. KNAPP said that tobacco had a peculiar selective action on the ganglion cells of the retina and on certain fibers of the optic nerve. At the same time, most cases of toxic amblyopia (retrobulbar neuritis) were due to the combined poisons of tobacco and alcohol. Instances in which this optic nerve lesion had been due to tobacco only were very unusual. This was further shown by the experience that toxic optic neuritis practically never occurred in Cuba or in Turkey, countries in which, as was well known, a great deal of tobacco was consumed. Dr. Knapp was interested in what Dr. Thompson had said in regard to tobacco not affecting blood pressure, and would like to ask Dr. Thompson whether he permitted his patients with arteriosclerosis to use tobacco.

Dr. THOMPSON replied that he tried to keep such patients within bounds. He did not think two or three mild cigars a day did them any harm. He agreed with what Dr. James had said as to intermittent use. A cigarette smoker kept himself constantly stimulated. His system was never free from nicotine. An intermittent user was free of nicotine between whiles.

Dr. JAMES said it was important to know definitely whether a cigarette was more pernicious than a cigar. His view was that the cigarette was better because there was less of it. In other words the difference was quantitative, not qualitative.

Dr. CLEVELAND said he believed the cigar did more harm because of the quantity.

Dr. A. A. SMITH thought that the cigarette smoker kept the mucous membrane constantly irritated by inhalations of the smoke.

Dr. J. C. ROPER said that the whole matter of toxicity had been investigated in the *Lancet* and that cigarette smoking had been found least harmful. The pipe had been condemned as holding the most nicotine.

Dr. JAMES asked was that observation founded on clinical experience?

Dr. ROPER said he was not sure of the exact details.

Dr. JOHN W. BRANNAN said that he remembered very well the report of the *Lancet* Commission referred to by Dr. Roper. The investigation and conclusions of the Commission were discussed at length in an editorial in the *New York Medical Journal*. Dr. Frank Foster was the Editor of the *Journal* at that time, about fif-

teen years ago, and was, as many members of the Society would remember, an habitual smoker of cigarettes, which he rolled himself. He noted with great satisfaction that the Commission found the cigarettes contained no injurious ingredients other than nicotine and that such nicotine as reached the mouth came principally, if not entirely, from the moistened tobacco in contact with the lips, which was undoubtedly greater in the cigar than in the cigarette. Foster stated that in his own experience and judgment injurious effects did not follow generally the moderate smoking of tobacco, whether as cigarettes or otherwise. Excess was bad, as in use of all other things. He believed that cigarettes *per se* were not more injurious than any other form of smoking, and, in his opinion, not so injurious as cigars, as they contained less tobacco. The only especial danger inherent in cigarettes was the temptation to a more continuous use and to the practice of inhalation. Dr. Brannan had noticed that evening, as often on other occasions, that there were more condemnations of cigarettes by cigar smokers, than by men who did not smoke at all. He did not think it mattered what was smoked if the amount of tobacco was kept within bounds. Their were patients who smoked cigars to excess—10 to 12 a day; that was more harmful than 12 to 20 cigarettes. If men would bear in mind the possibly injurious effects of inhalation less harm would be caused by the cigarettes. He believed that the practice of inhalation was much less common than formerly. Certainly he saw little of it among men of mature years.

Dr. BACON said he had understood Dr. James to say earlier in the evening that a man was much affected by his first smoke, and not at all later. In his own case he had still to be careful to choose a mild cigar, and could not stand a strong cigar at all.

Dr. JAMES asked if anyone had noticed that hypersensitiveness to tobacco went with a predisposition to seasickness.

Dr. THACHER said that was not so in his case. He did not get seasick but he could not stand tobacco.

Dr. THOMPSON said he would defend pipe smoking as usually an out-door form of smoking, and therefore less injurious.

Dr. KNAPP said he wanted to know what was the form of tonic treatment Dr. Abbe had alluded to for "cigarette fiends" in the West.

Dr. ABBE said he did not know definitely, but he thought the throat was swabbed with nitrate of silver, a mouth wash was given, and some tonic was administered.

Dr. THACHER asked whether this treatment worked in the same way as washing a child's mouth with soap, which tended to prevent bad language.

Dr. PECK said that in studying his cases of duodenal ulcer, he had come to recognize a group of habitual cigarette smokers, who were not especially alcoholic, as subject to this disease. They were generally young adults, foreign born or of foreign parentage, who habitually smoked from 20 to 40 cigarettes or more a day. Whether this lesion depended on digestive disturbances, which made the gastric secretions and contents more irritating and caustic, or lowered the resistance of the tissues, he could not say. The frequency of the lesion in this group of cases was striking enough to be comparable to ulcer in alcoholics, especially those who were addicted to whiskey and hard liquors in concentrated form. In this latter class of cases the local chemical irritant effect of the stomach contents was undoubtedly an important etiological factor, as the ulcer almost invariably occurred at the point on the duodenal wall against which the chyme was projected in spurts as it passed the pylorus.

Dr. M. A. STARR said that nothing had been said in regard to the literature. Professor Fraenkl-Hochwart of Vienna, in the *Deutsche Zeitschrift für Nervenheilkunde*, Vol. 47, p. 128, had an interesting article on the effects of tobacco on various organs of the body.

Dr. THACHER said, in regard to differences between different brands of cigarettes, that in Paris, a few years ago, he met one of the prominent neurologists at a luncheon. This physician had recently been called to Constantinople to advise regarding the long ago deposed sultan. This sultan was a neurotic and not thought fit to head the government. The government, however, were anxious to do what they could for his health and comfort. The patient was an excessive cigarette smoker. The government wanted to know if any form of cigarettes was less injurious than others and if so, which, and asked that no pains nor expense be spared

to advise them on the question. On returning to Paris, the neurologist had investigations, chiefly chemical, made on the different types of cigarettes. The chemist reported varying proportions of nicotine and the presence of opium in every brand of cigarette except one certain kind, which contained very little nicotine and no opium. The host then said that he could smoke this brand without experiencing the ill effects which he experienced from other kinds. In regard to another of the stimulants which had been mentioned in this group, an English physician had published a monograph to show that since the introduction of tea into England the English people had shown marked intellectual improvement.

Dr. ABBE said his attention had been called to the subject by the increase of mouth cancers in immoderate smokers. In these persons 9 cancers out of 10 were caused by tobacco. It was not seen in moderate smokers. He always persuaded the patients to give up tobacco, saying that he could do nothing for them if they persisted in smoking. In leukoplakia, a precancerous condition, he made the patients give up smoking. They always agreed to give it up instantly.

Dr. JAMES said that Dr. Abbe had the threat of cancer to hold over his patients; that was more powerful than merely threatening digestive disturbance. Speaking of snuff, Dr. James said he had heard that the capital of the American Snuff Company was 60 million dollars. It seemed incredible that people should take snuff to that amount.

Dr. ABBE said that in the South "dipping" was common.

Dr. A. A. SMITH asked Dr. Abbe if he had any observations of cancer of the mouth in women, since the custom of women smoking had become so prevalent.

Dr. ABBE said that he had seen cases of cancer of the lip or gum from cigarette smoking. Cancers did not occur in moderate smokers, but frequently in excessive smokers. In all cancerous conditions Dr. Abbe said he stopped the patient smoking, as the circulation of nicotine in the blood caused irritation and might hasten cell growth.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE TEXAS STATE BOARD OF MEDICAL EXAMINERS.

June 22, 23, and 24, 1915.

(Concluded from page 134.)

PATHOLOGY.

1. What is a tumor (new growth)? (a) Classify tumors as to the tissues from which they arise. (b) Give examples.
2. What constitutes malignancy? (a) By what channels are metastases carried?
3. Describe the stages of simple inflammation.
4. Describe the pathological process leading to destruction of the valve in mitral insufficiency.
5. Give in detail the blood picture of pernicious anemia.
6. What systemic pathological changes are usually associated with contracted kidney? (Interstitial nephritis.)
7. Give the pathological changes in the intestines in typhoid.
8. Describe the gross and microscopical appearance of a gumma of the liver.
9. Describe in detail the pulmonary changes in the various stages of croupous pneumonia.
10. Give pathological changes in amebic dysentery.

PHYSICAL DIAGNOSIS.

1. What are the methods of physical diagnosis?
2. By what symptoms would you diagnose Pott's disease (of spine)?
3. Give use of sphygmomanometer. (b) What is blood pressure?
4. State in what diseases we would most likely observe hypertension and hypotension.
5. Describe the characteristics and significance of the several kinds of arterial pulse.
6. Differentiate organic and functional heart murmur.
7. What are the normal sounds obtained by percussion on the thorax?
8. In what diseases can we employ the microscope as an aid in diagnosis?

9. What are the physical signs of sciatica?
10. What are the physical signs of pellagra?

SURGERY.

1. Difference between acute abscess and carbuncle; organisms usually present in both.
2. Preparation of patient for abdominal section beginning thirty-six hours beforehand. Give after-treatment.
3. Define acute osteomyelitis—give treatment and differential diagnosis between it and acute rheumatism.
4. Treatment of simple fracture at junction of upper with middle third of femur.
5. Diagnosis of chronic duodenal ulcer.
6. What surgical complications may arise in typhoid fever?
7. Differential diagnosis between tuberculous kidney and stone in kidney.
8. How would you put an old man in best physical condition for removal of prostate?
9. Treatment of penetrating wound of right chest.
10. A man receives a blow on top of head; you are called in and observe him unconscious, and with a scalp wound; how would you handle the case?

MEDICAL JURISPRUDENCE.

1. Define rigor mortis; say where it commences, how long it lasts, and its importance from medicolegal standpoint.
2. Differentiate the male and female skeleton.
3. How would you determine whether a stab wound on dead body was made before or after death?
4. What points would help to determine whether a gunshot wound was self-inflicted?
5. Under what conditions may pregnancy become a subject of medicolegal inquiry?
6. Under what conditions is the destruction of a living fetus not considered murder?
7. Give the classifications of insanity.
8. In suspected infanticide how would you determine that the child was born alive?
9. In case of doubtful paternity what points would help to fix the responsibility?
10. Upon what evidence could you sustain a charge of recent abortion?

HYGIENE.

1. Name some of the diseases believed to be acquired by inhalation of microorganisms from the air.
2. How much O does an adult human being at rest ordinarily take from the air and how much CO₂ does he add to it in twenty-four hours? (a) How would you arrange for natural ventilation of a schoolroom during cold weather?
3. What quantity of water should be supplied per capita daily by towns and cities for all purposes? (a) Mention some diseases that are frequently transmitted by water.
4. What is the probable significance of nitrites or nitrates in water?
5. How is milk most frequently adulterated, and what is the greatest danger in such adulteration?
6. What conditions may render meat unfit for food?
7. Of what disease or diseases is the house-fly a carrier?
8. What precaution should be taken in locating the well or cistern for drinking water on a farm?
9. What precautions should be taken in the handling of a case of typhoid to prevent the infection of others? (Explain fully.)
10. Describe a reliable method for the disinfection of a room which has been occupied by an infectious patient.

ANSWERS.

PATHOLOGY.

1. A tumor is a pathological new growth which tends to persist independently of the structures in which it lies, and which performs no physiological function. Tumors may be classified as follows:

I. Those derived from the mesoblast:

- (a) *Benign*: Lipoma (from fat tissue), fibroma (from fibrous tissue), chondroma (from cartilage), osteoma (from bone), myoma (from muscle), neuroma (from nerve tissue), glioma (from neuroglia), angioma (from vessels).

- (b) *Malignant*: Sarcoma (from connective tissues).

II. Those derived from the epiblast or hypoblast:

- (a) *Benign*: Adenoma (from gland tissue), papilloma (from papillæ of skin or mucous membrane).

- (b) *Malignant*: Carcinoma (from epithelial tissues).

2. *Malignant tumors* are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

Metastases are carried by the lymphatics and by the blood vessels.

3. The phenomena of inflammation are dilatation of the arterioles, capillaries, and small veins. At first the blood current is quickened, then retardation occurs, and may progress to stasis and thrombosis. During this time exudation of plasma and white corpuscles from the small veins, and perhaps the capillaries, is going on. The fate of the white cell may be either to break up and set free prothrombin, or to act as food for connective tissue cells, or to act as a phagocyte and be transformed into a pus corpuscle. Red corpuscles may be exuded and broken up, setting free their coloring matter. The prothrombin of the white cells unites with the calcium chloride of the plasma and forms thrombin, or fibrin ferment, which acts upon the fibrinogen of plasma to form fibrin.

The tissues are thus invaded with numbers of leucocytes. In bacterial inflammation a varying portion of the tissues is killed by the toxins produced, and is either replaced by a mass of small round cells, or liquefied into pus. In the latter case it is surrounded by a ring of small round cells. The connective tissue cells absorb the leucocytes, and new vessels are formed, thus constituting repair. In nonbacterial inflammation, exudation may separate layers of cells to a large extent and form blebs. In chronic inflammation the formation of new fibrous tissue is the chief part of the process.—(From *Aids to Surgery*.)

4. *Pathological processes leading to destruction of valve in mitral insufficiency*: "In those cases not directly attributable to acute endocarditis, the changes briefly are: (1) Formation of small nodular prominences, with thickening of the valve. (2) Formation of yellowish, opaque, fatty patches. (3) Great increase of fibrous tissue, which subsequently contracts, producing much deformity. The cusps become rigid, curled, and may cause great obstruction to the onward flow of blood, and at the same time fail accurately to close together when required. (4) Great narrowing of the valvular orifice. (5) Shortening of the chordæ tendineæ and papillary muscles. Frequently fusion of the chordæ tendineæ (adhesions). (6) Calcification of the fibrosed portion."—(Wheeler & Jack's *Handbook of Medicine*.)

5. In *pernicious anemia* the blood would show: (1) A diminution in the number of red corpuscles; (2) a relative increase in the amount of hemoglobin; (3) poikilocytosis; (4) the presence of nucleated red cells; (5) variation in the size of the red cells; (6) the leucocytes may be diminished.

6. The systemic pathological changes usually associated with contracted kidney are: "The left side of the heart is hypertrophied, and there is also hypertrophy of the muscular fiber of the arterioles throughout the body; if the case is protracted, the hypertrophied tissues undergo fatty degeneration. Cardiac degeneration with arteriocapillary sclerosis or fibrosis is associated with advanced nephritis. The changes in the arterial walls lead to apoplexy, albuminuric retinitis, and fatty degeneration and atrophy of the ganglionic centers."—(Hughes' *Practice of Medicine*.)

7. In the first stage of typhoid fever Peyer's patches become swollen, hyperemic, and reddened; a few days later they appear as whitish or gray elevations, and the hyperemia has disappeared; the surface of the patch is smooth and its edge is sharply defined; after the first week necrosis may occur; the center of the patch becomes softer, more yellow, or sometimes even red from the absorption of blood pigment. The necrotic portion falls off, leaving an irregular ulcer, with necrotic and undermined edges. These ulcers are elongated, with the long axis parallel with that of the intestine, and a smooth floor. The ulcers may heal or go on to perforation.

8. *Gumma of the liver*: "The gummata range in size from a pea to an orange. When small they are pale and gray; the larger ones present yellowish centers; but later there is a 'pale, yellowish, cheese-like nodule of irregular outline, surrounded by a fibrous

zone, the outer edge of which loses itself in the lobular tissue, the lobules dwindling gradually in its grasp. This fibrous zone is never very broad, the cheesy center varies in consistence from a gristle-like toughness to a pulpy softness; it is sometimes mortar-like, from 'cretaceous change' (Wilks). They may be felt as large as an orange beneath the skin in the epigastrium and they may disappear with the same extraordinary rapidity as the subcutaneous or periosteal gumma. Microscopically they may indeed at first look like massive cancer. Extensive caseation, softening, and calcification may occur. The syphilitic scars are usually linear or star shaped. They may be very numerous and divide the liver into small sections. The syphilitic cirrhosis is usually combined with gummata, or with marked scarring in the portal canal, leading to lobulation of the organ, but the ordinary multilobular cirrhosis is not common. (DODGE'S *Practice of Medicine*.)

9. **ACUTE LOBAR PNEUMONIA.** "It is convenient to describe four stages, those, namely, of (1) hyperemia or engorgement, (2) red hepatization, (3) gray hepatization, and (4) resolution. *First stage or splenization.*—The lung is injected, dark red, and heavy, and pits under the finger; on pressure, there exudes a frothy serum tinged with blood and slightly aerated. The lung still floats in water. *Second stage or red hepatization.*—The part involved is solid and friable, presents a granular or red granite appearance, and sinks in water. The alveoli are filled with a coagulated exudation, which shows under the microscope fibrin, leucocytes, red corpuscles, proliferated alveolar epithelium, and pneumococci. *Third stage or gray hepatization.*—The lobe has now the appearance of gray granite, the lung substance is softer and more friable; on pressure, a dirty purulent fluid exudes. The gray appearance is due to four factors: (1) Decolorization of the red blood corpuscles; (2) obliteration of the alveolar blood vessels from pressure; (3) fatty degeneration of the coagulated material; (4) great infiltration of leucocytes. A more advanced stage, in which the lung tissue is bathed in purulent fluid, is known as purulent infiltration. It is probably inconsistent with life. *Fourth stage or resolution.*—Resolution of the inflammatory exudation is brought about principally by absorption (autolysis), but partly by liquefaction and expectoration. Pneumonia may affect a lobe, or the whole of a lung, or it may attack both lungs. Double pneumonia occurs in about 10 per cent. of cases. Different parts of the same lung may at the same time show different stages. There is always some degree of pleural inflammation over the affected area. Modern enlargement of the spleen is very common."—(Wheeler and Jack's *Practice of Medicine*.)

10. "In *amebic dysentery* the lesions are situated in the colon, but may be found in the ileum. Ulceration, involving the mucosa and submucosa, is the characteristic structural change. This process is preceded by the infiltration of the mucous and submucous coats with a grayish, gelatinous substance, the exfoliation of which produces the ulcer. In the early stages these local infiltrations appear as hemispherical elevations, the mucous membrane covering which is soon cast off to be followed by sloughing of the submucous coat and its infiltrate. The microorganisms are present in the necrotic tissue and by their migration not infrequently (20 per cent.) produce abscess of the liver."—(Hughes' *Practice of Medicine*.)

PHYSICAL DIAGNOSIS.

1. Methods of physical diagnosis are: Inspection, palpation, percussion, auscultation, mensuration, and weighing. *Inspection* shows the shape, size, symmetry, movements, and color of the chest. *Palpation* confirms and adds to what is learned by inspection, shows areas of tenderness, condition of chest walls, presence of tumors, action of heart, and the existence and character of fremitus. *Percussion* shows the composition of structures or tissues, the resistance or elasticity of certain organs, and resonance of lungs. *Auscultation* enables one to study the condition of the heart and lungs.

2. *Pott's disease of the spine* may be diagnosed by: The local pain or ache at the site of the disease; it is made worse by jarring, or pressure on the head; girdle-pain or stomach-ache may be present; muscular rigidity; angular displacement at the site of the disease; abscess; and, sometimes, paraplegia.

3. The use of the *sphygmomanometer* is to estimate the blood pressure of a patient. *Blood pressure* is the

pressure exerted by the blood against the wall of the vessel in which it is contained.

4. *Hypertension* may be observed in: Chronic interstitial nephritis, arteriosclerosis, uremia, gout, lead poisoning, cerebral hemorrhage.

Hypotension may be observed in: Shock, collapse, concealed hemorrhage, anemia, acute infectious diseases.

5. (1) *Frequent pulse*: In fevers, exophthalmic goiter, early phthisis, heart disease, anemia, chlorosis, locomotor ataxia, abuse of alcohol, tea, coffee. (2) *Slow pulse*: In cardiac disease, cerebral tumor or hemorrhage, meningitis, myxedema, epilepsy, some poisons, digestive disorders. (3) *Intermittent pulse*: In cardiac disease, fevers, poisons, neurasthenia, cerebral troubles, digestive disturbances. (4) *High tension pulse*: In arteriosclerosis, gout, diabetes, contracted kidney. (5) *Low tension pulse*: In fevers, anemia.

6. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic or functional* murmur, and denotes as a rule an impoverished condition of the blood.

7. *Normal percussion notes*: "The apices yield normally a resonant note, clear but not intense and tending to rise in pitch (dullness) as the pleximeter finger approaches the vertebral line posteriorly, or the trachea, anteriorly. The infraclavicular space is typically resonant, and the pitch of the percussion note is slightly higher upon the right than upon the left side. Any tendency to approach the region of a primary bronchus results in a note of heightened pitch, increased resistance, and shortened duration (dullness). Below the right second rib anteriorly there is increased resonance until the fifth rib is reached, when the pitch rises because of the underlying solid tissue of the liver. At the sixth rib resonance ceases and a line of absolute dullness marks the lower limit of the lung and the upper border of the uncovered surface of the liver. In the axillary region typical pulmonary resonance persists until the eighth rib is reached. The cardiac area markedly modifies the percussion note of the left chest anteriorly from the lower border of the third rib downward within the nipple line; anteriorly along the whole internal boundary of the lung the note rises as one approaches the sternum."—(Greene's *Medical Diagnosis*.)

8. The microscope may be employed as an aid to diagnosis in: Typhoid fever, malaria, cholera, tuberculosis, amebic dysentery, diphtheria, anemia, chlorosis, leukemia, various forms of intestinal parasites, gonorrhea, influenza, tetanus, asthma, pneumonia, trichinosis, anthrax, actinomycosis, Bright's disease, syphilis.

9. *Symptoms of sciatica*: "Onset usually sudden, with pain in the back of the thigh, running down the course of the nerve. It may extend up into the lumbar region, but is most marked in the thigh. Motion increases it, and consequently the pelvis tilts up toward the sound side and the trunk leans over toward the affected side (sciatic scoliosis). The pain is dull and almost continuous, with paroxysms in which it is sharp, lancinating, burning, and of great severity. There may be sensations of tingling, numbness, and a sense of weight and coldness in the affected limb. There are tender points at the sciatic notch, the middle of the hip, behind the knee, in the middle of the calf, behind the external malleolus, and on the back of the foot. Rarely there is anesthesia along the course of the nerve. There may be weakness and muscular atrophy in chronic cases, and occasionally a partial De R. The duration of the disease is usually 2 or 3 months, although it may last for a year or more."—(Butler's *Diagnostics of Internal Medicine*.)

10. In *pellagra* "the symptoms develop insidiously, the earliest manifestations usually being gastro-intestinal—anorexia, stomatitis, salivation, epigastric pain or distress, diarrhea, and a gradually increasing anemia, disinclination to exertion, and psychic depression. The fully developed disease is characterized by cutaneous, digestive, and nervous symptoms. There is at first a characteristic pellagrous erythema that usually comes on first in the spring, tends to subside

and recur (in the fall and spring). It develops bilaterally especially on the exposed surfaces, the hands, arms, face, and neck; that is, it seems to be related to the action of the actinic rays of the sun; it may be dry (usually early) or wet; the lesions become pigmented (liver yellow or chocolate color) and usually progress to desquamation, exfoliation, and gangrene of the skin, which are followed by cicatrization. The characteristic digestive symptoms consist of stomatitis, the cardinal red tongue, the bald tongue, or the stippled, bluish black tongue; salivation, pyrosis, and diarrhea (fetid, slimy, greenish stools), sometimes bloody stools, may occur. The nervous symptoms consist of neuromuscular pains in the back and legs, spinal tenderness, headache, vertigo, unilateral or bilateral mydriasis, muscular spasms, exaggerated reflexes, later paralysis with lessened or absent reflexes, mental depression, delusions, hallucinations, melancholia, and insanity. Mild cases may be afebrile, but fever (102° to 105° or more) is not uncommon. Improvement may occur after the lapse of several months, but recurrences especially in the fall and spring are common."—(Kelly's *Practice of Medicine*.)

SURGERY.

1. "A *carbuncle* is a localized inflammation of the subcutaneous tissue, which goes on to sloughing, and is of a more extensive character than a boil. Staphylococci are the common exciting cause, while the predisposing causes are lowered vitality from diabetes, albuminuria, or after infective fevers. Inoculation is by autoinfection or directly from the surface. *Signs*: The disease begins as an infiltration of a patch of subcutaneous tissue, which is hard, painful, and tender, and the skin over it is red and hot. The infiltration may extend till it is the size of a dinner-plate, and the inflammation ends in sloughing and suppuration, not only of the subcutaneous tissues, but of small areas of the skin over it, so that openings develop in the skin, and allow of the exit of pus and sloughs. The openings extend, the sloughs separate, and the wound heals by granulation. The back is a common situation. Sometimes the face is affected, and there is then a danger of thrombosis extending to the cavernous sinus and producing pyemia."—(*Aids to Surgery*.)

An *abscess* is a localized collection of pus in a cavity of new formation. It is, therefore, walled off; if near the surface it fluctuates; it may occur at any period of life, whereas the carbuncle commonly occurs after forty years of age; the abscess may be caused by staphylococci, streptococci, or any other pus-producing organism; abscess does not cause the severe constitutional symptoms which may be observed in carbuncle.

2. *Preparation of patient for abdominal section*.—"If possible, the patient should be under observation for at least 24 hours prior to the operation. During this time a careful study is made of the urine and the condition of the heart and lungs, and necessary treatment instituted. The diet should be restricted, and a purgative given the night before, followed by an enema on the morning of the operation. No breakfast, or merely a cup of beef-tea, should be given on the day of the operation. The abdomen should be shaved and scrubbed thoroughly with tincture of green soap and sterile water for at least 10 minutes on the night before the operation. A general bath should then be taken, giving special attention to the inside surfaces of the thighs and to the umbilicus. A soap poultice is applied to the abdomen and allowed to remain for several hours; this is removed, and the abdomen is scrubbed with alcohol and washed with mercuric chloride solution (1:1000). A towel wet with this solution is placed over the abdomen, and a binder is applied.

"If any operation is to be done that will involve opening the vagina—such as total extirpation of uterus—the patient, after being anesthetized, should be placed upon the perineal pad, and the vagina should be thoroughly scrubbed with a piece of gauze held in a dressing forceps, previously dipped in green soap. After the scrubbing the soap should be washed out and the vagina syringed with a 1:2000 sublimate solution. If there is any septic material coming from the uterus, as in cancer of the body, the uterus should be first thoroughly curetted and packed with iodoform gauze. A cancerous cervix should also be curetted, disinfected, and the vagina lightly packed with iodoform gauze.

"All water, basins, trays, aprons, gowns, sheets, sponges, pads, drains, dressings, and everything with which the abdominal wall or the surgeon comes in contact should be carefully sterilized."

After-treatment: "The patient is placed in bed, and

care is taken to prevent shock by the application of artificial heat. Nothing but water should be given by the mouth for 24 hours. Pain is relieved by morphine, gr. $\frac{1}{4}$, hypodermically. Liquid diet is preferred for the first week, at the end of which the stitches are removed. The bowels are opened upon the third day by fractional doses of calomel, followed in 12 hours by a saline laxative and an enema. The patient should remain in bed for from 2 to 3 weeks."—(*Pocket Cyclo-pedia*.)

3. *Osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone. The *treatment* consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

Symptoms: Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present.

It is to be *diagnosed* from *Rheumatism*, in which more than one joint is affected and the tenderness is in the joint, and not near it.

4. *Treatment of simple fracture at junction of upper with middle third of femur*: First of all, prevent the fracture from becoming compound; then reduce it; coapt the edges of the broken bone; immobilize the parts, and attend to the general condition of the patient. Splints and weight extensions may be required.

5. In *ulcer of the duodenum* the symptoms are very similar to those found in ulcer of the stomach; but in the former condition there is less tendency to vomit, the pain does not come on till some time after food has been swallowed (and has had time to pass the pylorus), and blood in the stools is more common. All of these points are due to physiological and anatomical reasons based on the relative position of the stomach and duodenum. A special sign of duodenal ulceration is the so-called "hunger pain" which occurs at the end of digestion, when the unmixed acid of the gastric juice is passing into the duodenum. This pain is relieved by taking food, for when this occurs the pylorus closes, and the gastric juice is for the time retained in the stomach to be mixed with the food, while the alkaline duodenal and pancreatic secretions are stimulated.

6. The surgical complications which may arise in typhoid fever, are: Perforation of the intestine, internal hemorrhage, peritonitis, and cholecystitis.

7. *The diagnostic symptoms of tuberculous kidneys* are: Frequent micturition, with pus, and sometimes blood in the urine; pain and tenderness over the kidneys, enlargement of kidney; chills, fever, and sweats; tubercle bacilli may be found in the urine; the cystoscope will show a retracted ureteral meatus on the affected side; the symptoms are not made worse by movement or improved by rest.

Stone in kidney: Symptoms consist of pain in the loins, markedly increased by exercise, especially on jolting. The pain may be referred to the thigh, groin or testicle. The colic is associated with hematuria, and often pyuria exists with frequency of micturition. The kidney may be enlarged, and tender on pressure. A large stone may exist without any symptom whatever. The most typical symptom consists in a sudden attack of excruciating and paroxysmal pain shooting down the loin to the bladder and testis. The attack is accompanied by vomiting, faintness, and collapse. Frequent efforts to pass urine are made, but only a scanty amount of blood-stained urine is passed. The pain ceases suddenly when the calculus slips back into the pelvis or reaches the bladder.

8. "If possible the patient should be kept at rest for three or four days before the operation, the bowels should be opened daily, and an enema given early on the morning of the operation, so that the rectum may be quite empty. Any bronchitis that may be present should be attended to, or in some cases which do not call urgently for relief, the operation should be delayed until the pulmonary symptoms have abated. In cases of cystitis, the bladder should, if practicable, be washed out once every day with a solution of silver nitrate 1:5000, followed by boracic lotion toward the end of the irrigation. If cystitis be absent, lavage is

neither necessary nor wise. For cystitis, certain drugs may be given with the object of lessening the alkalinity of the urine, and of making the interior of the bladder less septic."—(Jacobson's *Operations of Surgery*.)

9. *Penetrating wounds of right chest:* The treatment in the absence of serious hemorrhage or the lodgment of a foreign body, is disinfection and suture of the external wound and immobilization of the affected side of the chest. Hemorrhage from the internal mammary or intercostal artery may be controlled by ligation, or by pushing a gauze sac between the ribs and filling the inner end of the sac with gauze so that when drawn upon it will make pressure from within outward. Excepting extensive wounds, bleeding from the lung is rarely fatal, as the bleeding is checked by collapse of the lung. In the absence of external hemorrhage serious loss of blood is diagnosed by the constitutional signs of acute anemia and a rapidly accumulating hemothorax. Cases of this sort have been treated by the introduction of a drainage tube in order to admit air and favor collapse of the lung, but in the presence of serious symptoms one or more ribs should be resected, and the wounded lung dealt with directly by sutures or gauze packing. Hemothorax of lesser degree, or that form due to hemorrhagic pleurisy or tumors of the lung or pleura, does not require special surgical treatment unless it causes pressure symptoms or becomes infected; in the former case aspiration, and in the latter resection of a rib and drainage would be indicated. Foreign bodies should be removed if easily accessible, and the same rules as to the examination of the vulnerating instrument, the clothing, etc., apply here as elsewhere. If the foreign body is not easily found, it should be allowed to remain, unless it gives rise to subsequent trouble, when it may be definitely localized by the x-ray and its removal effected, if such be deemed advisable. With the exception of pneumocele, the complications of injuries to the chest are inflammatory in nature, viz., cellulitis, pleurisy, empyema, pneumonia, abscess or gangrene of the lung, mediastinal abscess, and peri-, myo- or endocarditis."—(Stewart's *Manual of Surgery*.)

10. "The treatment during the stage of collapse is the application of external heat and the administration of stimulants as in shock. Alcohol, however, should not be given, because of its exciting effect on the brain, and care should be taken not to overstimulate. When reaction has been obtained, the patient should be kept in bed in a quiet room, an ice bag placed on the head, the bowels opened with a purge, and the catheter used if there is retention of urine. The diet should be fluid, and sedatives used if necessary. If unconsciousness is prolonged, a suspicion of greater injury than concussion should always be entertained. After severe concussion the patient should avoid mental exertion for a number of weeks or months."—(Stewart's *Manual of Surgery*.)

MEDICAL JURISPRUDENCE.

1. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours. It usually begins in the muscles of the eye, neck, and jaw; then the muscles of the chest and upper extremity, and last of all those of the abdomen and lower extremity are affected. It passes off in the same order in about twenty-four hours. It is said to be due to the coagulation of the muscle plasma.

Medicolegally, it is a sign of death, and an indication of the length of time that has elapsed since death occurred.

2. The features of the bony skeleton which characterize sex, are: (1) In the male the bones are, as a rule, stronger, larger and heavier, and the prominences, ridges, and lines are more distinct; (2) the skull in the male looks more mature, and less like that of a child, and the glabella is more prominent; (3) in the female the sternum is shorter, the capacity of the thorax is less, and the upper ribs are more movable; (4) in the female the clavicle is shorter, thinner, smoother, and less curved; (5) in the female the sacrum is relatively wider, less curved, and is directed more obliquely backwards; (6) in the female the pelvis is wider, shallower, has an oval inlet, has a larger subpubic angle, the obturator foramen is triangular (oval, in the male), the tuberosities of the ischia are everted; (7) the inclination of the shafts of the femora from the pelvis to the knee is greater in the female.

3. In a stab wound inflicted before death, there will be retraction of the skin and muscles, arterial hemorrhage; the wound will have everted edges; large blood clots may be present; signs of repair or of inflammation may be present.

In a stab wound inflicted after death, there will be no retraction of skin or muscles, and no eversion of the edges (unless from putrefaction); the hemorrhage will be venous; blood clots are small; and there are no signs of repair or inflammation.

4. *Points which help to determine whether a gunshot wound was self-inflicted:* The location of the wound; the distance at which the shot was fired; the character of the wound; the burning of clothing, skin or hair; the embedding of grains of gunpowder; the presence or absence of the weapon; the position of the body when the wound was received; and certain surrounding circumstances which may have a bearing on the case.

5. "The occasions in which pregnancy becomes the subject of medico-legal inquiry are the following: (1) A woman may declare herself pregnant with an heir to an estate, for the purpose of defrauding other heirs at law; (2) for the purpose of extorting money from a seducer or paramour; (3) to stay the infliction of capital punishment until after delivery; (4) the plea of pregnancy may be set up as an excuse for non-attendance at a trial, to awaken sympathy, etc.; (5) an accusation of pregnancy may be made against a single woman, or one living apart from her husband, which may result in an action for damages for slander; (6) accusations of malpractice may be made against a medical man for error in diagnosis of pregnancy, or an attempt to bring on an abortion. On the other hand, pregnancy may be concealed (1) in order to procure abortion or infanticide; (2) in order to avoid disgrace."—(Reese's *Medical Jurisprudence*.)

6. When abortion is undertaken by properly qualified physicians after due consultation with other physicians, and for the purpose of saving the life or health of the mother, it is *justifiable*; under all other circumstances it is *criminal*. The former is a perfectly lawful medical procedure; the latter is illegal.

7. *Insanity* is "that state of disordered mind in which a person loses the power of regulating his actions or conduct according to the ordinary rules of society."—(Taylor.)

"The best classification for legal purposes"; (1) Idiocy; (2) imbecility; (3) mania; (4) melancholia; (5) monomania; (6) general paralysis of the insane; (7) dementia; (8) certain forms of mania without distinct etiological relations.—(Dwight's *Medical Jurisprudence*.)

8. *Application of hydrostatic test, to determine whether a dead infant was born alive:* "Having opened chest, note position of lungs (before respiration they occupy a small space at upper and posterior parts of thorax); their volume (of course increased after breathing); their shape (before respiration, borders sharp or pointed; after it, rounded); their color (before breathing, brownish-red; after it, pale red or pink); their appearance as regards disease and putrefaction; and whether they crepitate on pressure (as they will after respiration). Take out lungs with heart attached, and place them in pure water having temperature of surrounding air. Note whether they float (high or low), or sink (slowly or rapidly). Separate them from the heart and weigh them accurately; then place them in water again, and note sinking or floating, as before. Subject each lung to pressure with the hand, and note sinking or floating again. Cut each lung in pieces and test floating again. Take out each piece, wrap it in a cloth, and compress with fingers as hard as possible, and test floating, etc., as before. The crucial test of perfect respiration is each piece floating after the most vigorous compression."—(King's *Manual of Obstetrics*.)

9. In case of doubtful maternity, the following points might help to fix the responsibility: Resemblance of face, features, voice, gesture, attitude, habits, deformities; absence of one of the "claimants" beyond the seas for a much longer period than that of the particular gestation.

10. It may be impossible to prove the fact of an abortion. The evidence will depend on the signs of a recent delivery and examination of the product of conception. If the case is a criminal one, and was carelessly performed, there may be evidence of the use of instruments, sepsis, etc.

Signs of recent delivery.—In the living: Woman is

more or less weak, and incapable of exertion; pallor; soft abdomen with relaxed skin, and lineæ albicantes; breasts, full, tumid, and secreting milk; presence of colostrum corpuscles in the milk; secondary areola; external genitals relaxed and tumefied; os uteri swollen and dilated; fundus hard and globular; lochial discharge; absence of fourchette; lacerated cervix. *In the dead:* Uterus enlarged, thick and soft; uterus contains blood, clots, and debris of decidua; tubes and ovaries congested.

HYGIENE.

1. Diseases believed to be acquired by inhalation of microorganisms from the air: Tuberculosis, pneumonia, diphtheria, measles, scarlet fever, whooping cough, erysipelas, influenza.

2. An adult, at rest, takes about sixteen respirations a minute; the tidal air is about 500 c.c. Therefore $500 \times 16 = 8000$ c.c. of air are respired in a minute. Inspired air contains 21 per cent. of oxygen; therefore $80 \times 21 = 1680$ c.c. inspired per minute, or $1680 \times 60 \times 24$, or 2,419,200 c.c. inspired per day. By the same method it may be calculated that an adult expires $352 \times 60 \times 24$, or 5,068,800 c.c. of carbon dioxide a day (4.4 per cent. of expired air being carbon dioxide).

Ventilation: "The principal means of ventilation are the windows, doors, and the artificial openings especially made for the purpose. The occasional opening of doors and the opening of windows greatly assist the exchange of air in ordinary dwellings, with not too many persons in the rooms and with but ordinary illumination and heating. When the number of persons in rooms is large and the number of lights increased, the windows and doors may not be sufficient for adequate ventilation, and special artificial openings may be needed. The number and character of such openings vary in size, location, shape, character, etc. The openings may be in the shape of tubes or boxes placed within the windows, the sashes, the panes, the walls at different points, the ceilings, or the floors. All such openings communicate with the external air, and serve as air inlets, or outlets, and may also be provided with adjustable gates, so that they may be closed up when not wanted. The number of ventilating devices is very large; their value depends on their location and size and character. Where local heating is used within the house, ventilation is aided by the necessary chimney and fire openings, and by the use of grates and stoves. The advantages of mechanical ventilation are the constancy of the exchange of air, the independence from any other means, the perfect control of the velocity and volume of the supplied air, the possibility to accurately regulate the temperature, quantity, moisture, and purity of the incoming air. Mechanical ventilation is, as a rule, carried on from a central point, and is of three kinds: *plenum*, or propulsion method, in which pure air is driven into the house from outside; *vacuum*, or exhaustion method, in which the impure air is withdrawn from the house; and the combined *vacuum and plenum* methods."—(Price's *Hygiene and Public Health*.)

3. "Fifty gallons of water per day is a safe average minimum, while in large cities and civilized communities a supply of 300 gallons and more per person is not excessive."—(Price.)

Diseases caused by the use of impure water are: Typhoid, cholera, dysentery, diarrhea, goiter, intestinal parasites, metallic poisoning, vesical calculi.

4. The mere presence of nitrites in water is suspicious, while the amount of nitrates must be marked before the water containing the same is regarded as suspicious. The presence of these salts in water indicates organic nitrogenous matter which has undergone chemical changes.

5. *Milk may be sophisticated or adulterated* by: (1) Skimming; (2) the addition of water; (3) the addition of coloring matter, such as caramel, annatto, or methyl orange; (4) the addition of preservatives, as boric acid, formaldehyde, salicylic acid, or salicylates; (5) the addition of arrowroot, flour, sugar, glycerine, chalk, or sodium carbonate.

The greatest danger in such adulteration is in the transmission of the microorganisms of infectious diseases which may be present in the dirty water with which the milk is diluted.

6. *Meat may be unfit for food* owing to: Disease of the animal; unfit condition and surroundings of living animals; post-mortem changes; infection of the meat by persons or places of manufacture, sale, etc.; and by adulteration. This last may consist in: "(1) Addi-

tion of foreign substances reducing, lowering, or injuring the quality of the food. (2) Partial or entire substitution of an inferior substance. (3) Extraction of some of the valuable substance from the meat. (4) Coloring, coating, or otherwise changing the appearance of the food, whereby poor quality is concealed, or it is made to look better than it is. (5) Addition of some foreign substance to 'preserve' it."—(Price's *Epitome of Hygiene*.)

7. *Diseases transmitted by flies:* Typhoid, cholera, plague, tuberculosis, dysentery, anthrax, and intestinal parasites.

8. In locating a well for drinking water on a farm, care should be taken that it is so situated that no water can flow into it from stables, manure pits, privies, cess-pools, cattle-pens, etc. Further, the well must be well covered; and all around its opening should be a properly cemented border.

9. To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put in water or other drink or food.

"When the patient has recovered from an infectious disease, he should be given a general bath with soap and water. In addition to this, he may be bathed with chlorinated soda solution, and in the exanthemata it may be advisable to anoint his body again unless all desquamation has ceased. After a general bath has been given the patient may be allowed to mingle with the well. In most localities the convalescent from certain diseases, especially smallpox, is washed with 1:2000 bichloride of mercury solution, clothed with clean clothing, and then transferred to a disinfected room.

"The clothing and bedding which are to be disinfected by means of steam should be carefully wrapped in cloths saturated with 1 per cent. carbolic solution, placed in a wagon, and taken to the disinfecting station. After the bed has been stripped, all refuse matter, paper, and articles of little value are wrapped in cloths saturated with carbolic acid and burned in a stove or furnace. The floor, doors, windows, furniture, and the walls for a distance of $1\frac{1}{2}$ meters from the floor should be washed with 5 per cent. carbolic acid solution. The walls and ceiling of the room should subsequently be sprayed with 1:1000 bichloride of mercury solution. If the walls are papered, it is advisable to remove carefully the paper before beginning the disinfection. The room is then closed as tightly as possible and disinfected by means of formaldehyde."—(Berger's *Hygiene*.)

10. *To fumigate by sulphur dioxide:* For each 1,000 cubic feet of space, three pounds of sulphur are burned, care being taken to prevent accidents. In every case all apertures and crevices of the room should be closed, all closets, drawers, or other receptacles opened; and after the fumigation the room should be well ventilated and thoroughly cleansed with a solution of corrosive sublimate.

Open Treatment of Wounds with Cellulose Rings.—Lörcher uses rings of cellulose covered with mull as an adjunct to the open treatment of wounds. The cellulose is first rolled up like a long sausage and then bent around in ring shape. Cotton wadding may be used in the same fashion. A mull bandage is then wound about. The rings are of various sizes and thicknesses. They are placed over the wounds and fastened on with a square of muslin fastened to the body with mastisol. In position they resemble large corn or bunion plasters. They are chiefly indicated for wounds involving the skin and soft parts. Naturally they are adapted only for dry dressings. They are superior to bandages in many localities—for example, near joints.—*Münchener medizinische Wochenschrift*.

THE VALUE OF TRANSFUSION IN ATROPHIC AND DEVITALIZED INFANTS AND CHILDREN.*

By LOUIS FISCHER, M.D.,
NEW YORK.

IN a certain class of infants of the marasmic or atrophic type, gastroenteric disturbances preclude successful feeding. In like manner toxicity associated with the acute infectious disorders renders the prognosis exceedingly grave. The infant loses day by day and the prognosis is correspondingly worse.

It is immaterial whether the condition is primarily due to faulty metabolism of fat or protein resulting in inanition, or whether we are dealing with a secondary anemia. The examination of the blood reveals the same clinical picture, *to wit*: decrease in the percentage of hemoglobin and marked decrease in the number of red blood corpuscles.

If the general condition improves, the blood picture improves. Here then lies our therapeutic indicator.

How can we best improve the blood? By increasing the power of food assimilation. But is this always possible? Decidedly not, otherwise our infant would not emaciate and go from bad to worse and lose weight. Human milk sometimes saves life provided sufficient can be assimilated.

As these cases offer little if any therapeutic hope one is compelled to lay aside drugs and food, and resort to emergency measures until an apparent crisis has been thwarted.

Another class of cases well adapted for this form of therapeutics is the toxic and the septic type of acute infectious diseases. Cardiac insufficiency resulting from the toxemia will frequently not respond to the routine method of stimulation. Strychnine with or without whiskey does not modify these symptoms. These desperate cases will succumb unless a fresh supply of blood is provided.

Another class of cases which lend themselves to this form of treatment is the hemorrhagic type of disease. Thus we utilize the intravenous injections in the hemorrhagic form of diphtheria.

The previous remarks may be considered my apology for bringing this subject before you for your consideration.

Recent literature records a great deal of progress in the completion of what may be regarded as an almost ideal method of transfusion. This method consists briefly in withdrawing from the donor, with the aid of a blunt-pointed steel needle and a record syringe, as many ounces of blood as desired for the transfusion. To prevent coagulation of the

blood a citrate of soda solution is added to it, and the whole kept at blood heat, in a sterile beaker until needed, or with the aid of Unger's apparatus direct transfusion can be done.

Hust in 1914 used a human blood transfusion by adding citrate of soda and glucose to the blood. Citrated blood was also recommended by Weil in 1914, who used 1 per cent. sodium citrate solution. R. Lewisohn found that 0.2 per cent. solution of sodium citrate will keep the blood fluid. His experiments with human blood transfusion were performed at the Mt. Sinai Hospital in New York.

The important fact gleaned from these experiments is that the addition of the citrate of soda prevents clotting.

The technique of the injection has been described by Dr. A. Zingher in the *MEDICAL RECORD* March 13, 1915. A suitable donor must be chosen. We have encountered no difficulty in procuring one of the parents or uncles to give eight to twelve ounces of blood. The donor must be free from syphilis or tuberculosis. If time permits, and the case is not a desperate one, we should determine if the serum of the donor agglutinates or hemolyzes the patient's red blood cells or *vice versa*. This method is described by Ottenberg and Epstein. In emergency cases as met with by me it was impossible to take the time to study the agglutination and hemolysis of the donor's blood. Ottenberg states that while it is better to test each donor's blood, he believes that danger exists in but 2 per cent. of all cases, or one in fifty.

The technique of transfusion is so simple that it can be successfully carried out in most cases by the general practitioner in the patient's home without any elaborate paraphernalia. But all must be done with sterile and aseptic technique.

The donor is placed in a recumbent position. A piece of rubber tubing and an artery clamp acts as a tourniquet above the elbow. To a 30 c.c. record syringe a steel needle one and one-half inches long is attached and inserted into the tense median cephalic vein. A syringe of blood is aspirated. The needle is left *in situ*. The barrel of the syringe detached, and the blood quickly emptied into a large beaker containing two and one-half c.c. of a 10 per cent. solution of sodium citrate. To keep the needle free, with the aid of a small record syringe inject a few drops of a 1 per cent. sodium citrate solution. Too rapid depletion is not safe and may result in a sudden cerebral anemia. It is much safer to allow the circulation of the donor to be re-established before withdrawing the second syringe of blood.

After each addition of blood to the citrate solution the beaker must be thoroughly shaken in order that the citrate may become thoroughly mixed with the blood. By the Unger method of blood transfusion we avoid drawing off the blood into a beaker, hence do not need the soda citrate solution. Clotting is practically avoided.

*Read by invitation before the Chicago Medical Society, Dec. 8, 1915.

When blood is drawn from the donor, saline solution is injected to replace the blood and to keep the needle free. The recipient receives not only blood but also saline.

The advantages of this method are:

1. The frequent handling of the cannulas is eliminated because connections are made not directly to them but to the cock. For this reason the cannulas ought not to be dislodged.

2. Clotting is avoided because the entire system is regularly and instantly flushed with saline, and the length of time the blood is outside the body is reduced to a minimum. In none of the animal experiments did clotting occur.

3. Only the operator handles the blood syringe. The function of the assistant is limited to the injection of the saline.

4. Fewer syringes are needed. In one experiment 800 c.c. of blood were transfused, only two syringes being used. It is advisable, however, to have about four to meet emergencies.

5. It is time saving because it reduces the manipulations; it minimizes the time the blood is outside the body, and it allows of the injection of saline simultaneously with the aspiration or injection of blood. When indicated, a more rapid transfusion can be done by this means than by any other method.

The rate of the flow can however be varied at will. Blood can be sent across as slowly as one wishes, because the patency of the circuits can be relied on.

Choice of Vein in an Infant. There are four places adapted for this method: (1) the median cephalic, (2) the median basilic, (3) the jugular, and (4) the longitudinal sinus.

The longitudinal sinus has been suggested by Tobler and Helmholtz of your city. Marfan as early as 1898 advised the use of this route for the intravenous administration of salt solution. Owing to the ease with which one can enter the sinus through the anterior fontanelle it seems as though Nature had left this opening as an emergency for this course of treatment.

My personal experience with this route dates back many years ago when, in conjunction with the house staff at the Sydenham Hospital, I used the intraventricular method of aspirating spinal fluid, and injecting by the same route, antimeningitis serum. This case was presented in the Section on Pediatrics of the New York Academy of Medicine March 10, 1910. The simplicity of this method is such that one can enter the sinus very readily. It is much easier to use this method than to resort to vein-to-vein, or artery-to-vein method.

In many of my cases the median cephalic vein was used. This being a very small vein in infants, it was necessary to make a small incision and expose the vein in order to inject the blood. The patient receives the blood directly into the vein. A 1 per cent. cocaine solution is used for local anesthesia. An incision is made at the bend of the elbow. The median cephalic vein is exposed, and the needle inserted, through which the blood is then injected. Some of my cases received but two ounces, others four, six, eight, and sixteen ounces at one transfusion.

The following cases will illustrate the types which have been selected, and which I believe offer a good method of resuscitation of many moribund cases:

CASE I.—Baby W., born Jan. 4, 1915, was asphyxi-

ated at birth and resuscitated with the aid of a pulmotor. It was a forceps case. Suffered cerebral hemorrhage. Prognosis hopeless. Received breast feeding, but was so weak that its first cry was noted when one month old. Always regurgitated or vomited its food. The infant when I first saw it was seven weeks old, and weighed seven and one-half pounds. It had an irregular, thready, and intermittent pulse, was fed with difficulty, was listless and cyanotic. The stools contained undigested particles of cheese and mucus. The circulation was bad, extremities cold, the heart sounds were feeble. Eight ounces of citrated blood were transfused. There was slight improvement in the color of the skin during the transfusion. On the following day the infant was brighter, had more color in the cheeks and ears, began to notice objects, and appeared more natural. Gained six ounces during the first week after the transfusion. The second week gained six ounces more. It is now over eleven months since the first transfusion, the child weighs over twenty pounds and has been discharged as cured.

CASE II.—Baby S., 2¼ years old, was seen by me suffering with influenza. In addition thereto there was a localized cervical abscess which required incision. Later marked hyperpyrexia, with temperature as high as 106°, continued for a number of days. The case was seen by Dr. Holt, who concurred in the diagnosis of toxemia from influenza. A few days later evidences of bronchopneumonia were noted. The exhaustion and de-vitalization due to the prolonged pyrexia so weakened the infant that the prognosis seemed grave. Transfusion by the direct method was used, six ounces of citrated blood injected into the median cephalic vein. Great improvement followed this transfusion within 24 hours. A striking fact was the drop in the temperature by lysis of one degree every three hours for the succeeding sixteen hours. Four days later another area of consolidation was noted and the temperature again rose. Packing and tubbing were used to reduce the temperature, but after one week more we again noticed evidence of exhaustion due to prolonged pyrexia, feeble pulse, muffled heart sounds, and general asthenia. As marked anorexia was noted I ordered gavage, using four to six ounces of peptonized milk. One day later a second transfusion of 7 ounces of blood was given. The same striking effect was again noted on the temperature, but the improvement most marked was on the pulse, on the heart action, and on the circulation of the extremities. Whereas the child previously was peevish and cross, it now became more contented and quiet. In this case three transfusions were given, and the child seemed to revive after each transfusion. Thus a hopeless condition before transfusion seemed to be modified within six hours after the blood was injected. The child succumbed to paralysis.

CASE III.—Rose G., 5 years old, was admitted to the Willard Parker Hospital with a temperature of 104°. She was ill six days with a severe toxic condition. The rash was a punctate erythema. The prognosis was hopeless. Nine hours after admission the temperature rose to 105°, pulse 164, respiration 44. An injection of 240 c.c. citrated blood from a parent was given. Six hours later her temperature dropped to 103°. On the following day the temperature dropped to 101°, although it rose to 104° on the evening of the same day. Three days after the first transfusion a second transfusion of 210 c.c. was given. The child seemed brighter, although the pulse and temperature were not markedly influenced by the second transfusion. Four days later 240 c.c. from an uncle was transfused. Within 24 hours the child's temperature, which before the third transfusion was 103.6°, dropped to 100.6°. The child made a slow convalescence. On the 27th day of illness the temperature was normal and remained so for two days. About two weeks after this transfusion a slight febrile disturbance appeared. There was a distinct chill, and a rise of temperature from 98.8° to 105°. The temperature then dropped to normal and remained so three days, when the same phenomenon was again observed, a chill followed by a rapid rise of temperature to 104°, and again the temperature dropped to normal. The spleen was enlarged. Three more days intervened, again a chill, followed by a rise to 106.4°. Quinine was given. The temperature then dropped to normal and remained normal. The child was discharged two weeks later in good health. A study of the temperature curve will show an interesting phenomena. That we had a recurrence of fever once every three days and the blood examination revealed the plasmodium. As this was the only case in the hospital, the inference was that the

plasmodium entered the circulation from the donor's blood.

CASE IV.—Ethel K., 3 months old, was admitted to the Willard Parker Hospital with marked opisthotonus, projectile vomiting, and all evidence of cerebrospinal meningitis. A diphtheritic exudate was seen on the tonsil. The culture showed the Kleb's Löffler infection. Lumbar puncture was attempted to control frequent convulsions. As the puncture resulted in a dry tap, we suspected a closure of the Foramen of Magendie. We aspirated the lateral ventricles and obtained from 50 to 60 c.c. of turbulent fluid, in which the *Diplococcus intracellularis* was found.* As we were dealing with a Klebs-Löffler infection in addition to a *Diplococcus meningitis*, the prognosis was hopeless. Notwithstanding this hopeless condition we were able to prolong life for many weeks by transfusing from 4 to 8 ounces of blood from the mother or father. The child died after a prolonged struggle.

CASE V.—Philip A. was admitted to the Willard Parker Hospital diphtheria service February, 1915. Diphtheritic membrane was seen on both tonsils and on the soft palate. The child was anemic and extremely emaciated. A soft systolic murmur was heard at the apex. The prognosis was hopeless.

Complications.—Pleuropneumonia was noted. The chest was aspirated and pus found. Exhaustion from inanition continued. A transfusion of 9 ounces of citrated blood was given by Dr. Zingher. The child lingered several days and finally died of exhaustion. Post-mortem examination showed a pulmonary abscess.

Incompatibility of Blood.—An accident that is possible in about 2 per cent. of cases is that the red blood cells of either the donor or recipient will hemolyze or agglutinate by the serum of the other. Ottenberg found, as a rule, that the blood on one person in every five or six examined was not entirely compatible with the recipients.

Hypertrophic and Dilated Heart.—Another condition that one should note is a danger caused by dilatation of the heart. When the heart is embarrassed, transfusion should be interrupted every few minutes. In a case of this character *syringe transfusion* would be indicated, rather than vein-to-vein or artery-to-vein transfusion. Ottenberg reports two cases of hypertransfusion, both fatal cases; one an endocarditis, the second a pernicious anemia. Large amounts of blood were transfused with fatal results.

Transfusion to Modify the Acute Infectious Diseases.—Any one who has seen the type of cases which exist among the poor and especially those neglected because of poverty or ignorance will have before him a type of septic or toxic cases as seen by us in the public hospital. Some of these cases are admitted in a moribund condition. Many more die within the first 24 to 48 hours regardless of any form of treatment, and it is to this class of cases, the so-called hopeless type, that we turn with some degree of optimism, hoping against hope. In a hemorrhagic case of diphtheria the patient, who was almost pulseless from nasal hemorrhages and did not respond to stimulation, was transfused by Dr. Leo Buerger, with the assistance of Dr. Ottenberg and the House Staff, at the Willard Parker Hospital. In this case the transfusion was direct. This patient responded to the transfusion but eventually died of toxic myocarditis.

Regarding the effect of normal blood during an acute infectious disease, much has yet to be learned. In some instances the blood of convalescents from scarlet fever† was utilized for both intravenous and intramuscular injections in the severer forms of scarlet fever, and it seems that there is more specific

bactericidal power in the blood of a convalescent than there is in the normal human blood. This leads Ottenberg to state that the blood of persons who have recovered from an infectious disease or who have been artificially immunized has specific properties not only in the antibodies of the plasma but possibly also in the cells.

Observation and Treatment of the Donor.—The pulse of the donor requires careful supervision whether we draw blood with a syringe or otherwise; less supervision, however, with the syringe method. Most of the men whom I have seen did best when they were blindfolded, as the sight of blood invariably caused nausea and sometimes syncope. The pulse is invariably slowed and should be watched for signs of collapse. Weakness was described by one donor when the second syringe of blood was withdrawn. We invariably stimulate the circulation after withdrawing eight ounces or a pint of blood by giving the donor one-half pint of milk with the yolk of egg added, or warm broth or coffee to which the yolk of egg is added. No other stimulation was necessary. It is important to have the donor rest at least an hour after withdrawing the blood.

I have utilized transfusion for the relief of de-vitalized and marasmic infants. Thus an infant seven weeks old was successfully transfused. This was my youngest case. The child was born in January, 1915, and transfused toward the end of February. It is alive to-day.

Influence of Fever.—A decided drop in the temperature followed in each of six transfusions (transfused cases). In one instance the temperature dropped from 104° to 100° within six hours. In another instance the temperature dropped three degrees within six hours by lysis. This decided anti-thermic effect could be accounted for in no other way excepting directly due to the influence of the fresh blood supply. Ottenberg and Libman have made a similar observation on the influence of transfusion on fever. "Of particular interest is the transfusion on the fever which is such a conspicuous feature of a large number of cases of pernicious anemia. It has been found in over 60 per cent. of the cases (in one report as high as 80). In 5 of the 6 febrile cases we investigated the fever disappeared after transfusion. This phenomena is not peculiar to this form of anemia, for among 16 other cases of anemia due to a variety of causes (including infections) febrile before transfusion, 8 became afebrile after it. These observations lend strong support to the view that there exists a fever dependent upon anemia as such, the so-called anemic fever. Transfusion is the best remedy for pernicious anemia; it never cures, but it leads to remissions in about half the cases."

The Advantages of Syringe Transfusion.—There are decided advantages in the direct or syringe method as advised by Lindeman, Zingher, and others. There is no traumatism, no pain, and a decided absence of shock. The most important point, however, is that the exact amount transfused is known.

Another advantage of the syringe method is that the donor's blood can be removed, mixed with an anti-coagulant such as citrate of soda, and then taken to the patient. This may be an important factor in securing blood from a donor who is sensitive about going to a hospital or who does not care to come in immediate contact with the recipient. This latter may be an important point if the patient

*Dr. Abrahams of the Research Laboratory aspirated and injected the patient in this case.

†See paper of Park and Zingher, read before the Medical Society of the State of New York, 1915.

(recipient) has an acute infectious disease which could be transmitted to the donor.

From the communication here presented I feel justified in making the following deductions:

1. That this is a very useful method of therapeutics.

2. That it can be used in the private house as well as the hospital.

3. That very little assistance is required.

4. That many marasmic and underfed infants and especially cases of secondary anemia are adapted to this treatment.

One striking point was forcibly brought out in the marasmic case under consideration. The infant's temperature was subnormal, the extremities cold. A general cyanosis was evident in the lips as well as fingernails and toenails. The circulation was stagnant. Within a few hours after the transfusion the cyanosis was lessened, the body temperature rose one degree, and this improvement continued and aided the general nutrition. I am therefore encouraged to believe that transfusion should be added to our therapeutic measures in marasmic infants.

It is a great pleasure to acknowledge the valuable association of Dr. A. Zingher and Dr. Abrahams of the Research Laboratory and the co-operation of Dr. C. T. Sharpe and Dr. W. K. Sharp and Dr. Franz of the Resident Staff of Willard Parker Hospital in furnishing clinical assistance and bedside notes.

155 WEST EIGHTY-FIFTH STREET

Lumbricoid Worm in a Tonsil.—A. B. Middleton reports the case of an eight-year old girl who was thin and anemic and suffered from "bilious attacks" lasting two or three days about every three weeks. The child did not complain of sore throat, but had an adenoid expansion and the tonsils were enlarged. An operation was undertaken for the removal of the latter. The right tonsil ruptured when the snare was tightened, and a female ascaris, 1½ inches in length, escaped. Within the tonsil was a cavity, the habitat of the worm. After the operation the bilious attacks ceased and the child improved in health.—*British Journal of Children's Diseases*.

INFLUENZA AND GRIPPE IN INFANTS AND CHILDREN.*

By CARL G. LEO-WOLF, M.D.,

BUFFALO, N. Y.

IN going through the literature on the subject of this paper, especially the pediatric literature, as one is apt to do in preparing a paper to be read before a body of learned men and physicians, I was struck at once by one fact, namely, that in the books published before the year 1890 I could not find any references, at least no extensive ones, to influenza or grippe, while beginning with that year these infections are described in every volume we open.

For the purposes of this short discourse, which is meant for a recapitulation and separation of clinical pictures, I have refreshed my memory and pieced out my personal clinical experience from the following volumes: Spiegelberg, in Pfaundler and Schlossmann, "Diseases of Children," second edition, 1912; O. Heubner, "Lehrbuch der Kinderkrankheiten," first edition, 1903; E. Feer, in his "Lehrbuch der Kinderheilkunde," first edition, 1911.

As can be gleaned from the title of this paper, I make a distinction between the two terms, "influenza" and "grippe," which have been considered by many to be but two names for the same disease or group of diseases. I trust, however, that I may be able to prove that this is a mistake, and that we have to deal here with two distinct entities, on the one hand an acute, contagious, and infectious, epidemic disease, "influenza," and on the other hand a group of numerous other contagious diseases, mostly of the respiratory tract, "the grippy infections," or as they are commonly called, "the colds." If we should insist upon using the name "grippe" for both types of infection, then we should accept Filatow's suggestion of classifying influenza as pandemic or epidemic grippe, and the grippy infections as endemic grippe; but, as stated before, I believe that by adhering to the distinction in names we will avoid many a mistake and misunderstanding on our own part as well as on the part of our patients.

History.—The history of medicine, than which there is, to my mind at least, no more fascinating nor instructive part of our science, records some eighty epidemics of influenza, which have been traced through the course of the centuries, and to those who are interested in this subject I would recommend the reading of "The Epidemiology of Influenza" by Professor Ditmar Finkler of Bonn University, in the fifteenth volume of the "Twentieth Century Practice of Medicine."

Suffice it for me to state here that the last extensive epidemic of influenza was the one, undoubtedly well though not favorably remembered by the older men here, in the years 1889 and 1890. This epidemic came from the steppes of Asiatic Russia, spread successively from east to west over the principal cities of Europe, and then, while it was making its appearance in the smaller communities of the old world, it followed the routes of rapid transportation to this side of the water, to make its appearance first in the city of New York, then in Chicago, Philadelphia, and Boston, whence it spread all over this continent.

Since then we have been able to observe sporadic cases of this disease as well as small epidemics

*Read at the meeting of the Cattaraugus County Medical Society at Salamanca, N. Y., January 14, 1916.

from foci where the disease had remained dormant, due to the fact that infected persons do not always become freed very readily from these bacteria, which may sometimes vegetate for months and even years in the human body, especially in the lungs in cavities and in bronchiectasies, and also in the accessory sinuses at the upper end of the respiratory tract. A few weeks ago another epidemic took its inception from Philadelphia, as it appears at present, and is now raging all over this country, and which has made me choose this subject for my paper.

The grippy infections are endemic, they are with us all the time, at least in the settled portions of the world, and to write their history we would have to go back to the time when man developed from a branch of the common tree of animal life, if not still further back.

Etiology.—Let us look first at the etiology of the two diseases. Influenza is caused by the *coccobacillus* of Pfeiffer, discovered in 1890; this is a very slender bacillus which grows only on media containing blood hemoglobin at temperatures between 76° and 106° Fahrenheit. Even on these media it can be kept alive only for about two weeks. In the specimen it is found in arrangements which have been compared to the schools of fish or to the flights of migrating birds; it is readily stained with carbol-fuchsin. The germ is found in the secretions of the mucous membranes in large numbers; in children it can be recovered from the blood, the various secretions, the cerebrospinal fluid, the pus from the ears, etc.

In the grippy infections we find at different times and in different endemics different bacteria, most frequently pneumococci, also the *Micrococcus catarrhalis*, the bacillus of Friedländer, streptococci, in fact, bacteria which live as saprophytic parasites in the mouth and the pharynx of healthy persons. Climatic changes, exposure, and improper clothing seem to play an important rôle in the development of these infections, as does anything which tends to lower the vitality of the system; thus we know that children with digestive disturbances, with exudative diathesis, and with scrofulosis are very prone to these infections, still the "genius epidemicus," as it used to be called in the pre-bacteriologic times, seems to be a quantity by no means negligible. I suppose most of you here can testify to the fact that you brought a grippy infection to your own penates from a patient who was so inconsiderate or so ignorant and so ill mannered as to cough or sneeze into your face; while, on the other hand, you can go into the wilds, fishing or shooting, be exposed to the inclemencies of the weather, stay in wet clothes day and night for any length of time, and yet not get infected, provided you have been careful in the choice of your companions and guides, and have seen to it that nobody in your party has a "cold." And then, having safely passed through all kinds of exposure, you may return to your home and to civilization and catch an infection from one of the members of your own family or from one of the first patients you see. This, at least, has been my own experience upon more than one occasion.

Transmission.—Both kinds of infection are transmitted by direct contact with infected persons, the germs are spread by sneezing, coughing, and talking, the so-called spray infection, and also by handkerchiefs; riding in street cars or traveling on railroad trains, the attendance at school or the

church, in short, all gatherings where large numbers of people are brought into close contact are the means of spreading these diseases. But while influenza does not seem to be dependent upon the climate nor the seasons, at least not any more than the other infectious diseases, the grippy infections appear regularly during the inclement weather of our late fall and last throughout the winter and early spring, though they may also appear in summer; in orphan asylums and in children's hospitals they are an extremely frequent occurrence. Here a new arrival or a visitor, nurse, or physician suffering from a so-called "cold in the head" will cause an endemic in the institution, and as the chances for these infections are thus very great it has been estimated that the inmates of these institutions will suffer from these infections, in some form or other, about once a month. This has been very aptly called hospitalism by my friend, Dr. L. F. Meyer of Berlin, and he has also shown that by certain measures, such as the exclusion of visitors, the wearing of gauze masks by physicians and nurses afflicted with a cold, and the separation of the infants by gauze screens, the so-called box system, we will be able to minimize the occurrence of these diseases.

Age also makes a considerable difference in the possibility of the transmission of the two diseases; influenza is mostly a disease of adults and older children, grippe is especially prevalent among infants and young children.

Pathological Anatomy.—Owing to the fact that we can but rarely obtain permission to perform a post mortem here, we have to depend largely upon European scientists for these investigations.

The pathological changes found in children dead from influenza are very little characteristic. Heubner describes them as follows: Usually we find more or less catarrh of the mucosa of the respiratory tract, with or without mucopurulent secretion; only the pneumonia following the serious cases is characteristic. Originally it is always lobular. We find a yellowish center in which there is usually a bronchus. This is surrounded by a reddish infiltrate, which is frequently hemorrhagic, sometimes the lobular inflammation becomes lobar from the confluence of a large number of lobular foci; the lung is very resistant to touch and has a multi-colored appearance on the cut surface; in the microscopical specimen we find the alveoli and the interstitial tissue engorged with round cells which contain the coccobacilli in large numbers. On the pleura we find mostly a fibrinous exudate and hemorrhagic foci; at times we may find a hemorrhagic or a purulent exudate; in some cases also abscess or necrosis of the lung.

In the grippy infections the pathological findings will be those of the secondary infections, such as the bronchopneumonia, the septic infections, such as meningitis from infection of the middle ear, which have nothing characteristic.

Symptomatology.—The typical symptoms of influenza in children, especially in the older ones, do not differ in any marked way from those in adults, and I therefore do not propose to take up your valuable time with a recital of things which you can read up in any textbook on the practice of medicine, provided it was not printed before 1890. What I intend to bring out to-day is the differential diagnosis, the atypical symptoms, the cases where you will be at sea when called upon to make a diagnosis, and where we, all of us, are the most

likely to make mistakes, and let me say, pardonable mistakes.

The younger the child the more atypical, the more protean will be the clinical picture. In young infants, who, by the way, seem to have a certain amount of immunity against the coccobacillus of Pfeiffer, especially when they are at the breast, the disease may be ushered in by vomiting, convulsions, and other symptoms of meningeal irritation. The symptoms from the alimentary tract will also prevail most frequently in the clinical picture in infants and young children, as the result of the indirect effect of the infection due to toxic irritation. We observe intestinal disturbances, such as constipation, soon to be followed by diarrhea and loss of appetite. The stools are more frequent and fluid and fetid, the prostration is profound, and if this should not happen during the height of an epidemic of influenza we may be wavering in our diagnosis between meningitis and typhoid.

As the child grows older the affection of the respiratory apparatus is more in evidence, which is due to the direct effect of the coccobacilli, which gain their entrance here, and this again will lead to many a mistake, or at least doubt in the diagnosis. Supposing you are called to see a child who has a conjunctivitis, a severe coryza, and a dry, barking cough, you hear that this little patient has never had measles; you know that at this time there is an epidemic of measles prevailing in your locality, while the epidemic of influenza is still in its inception; you examine the child carefully, and fail to find Koplik's spots, but instead of these you see a diffuse redness and a retropharyngitis; add to this a mottled appearance of the child's skin. What more natural than to make a diagnosis of measles? We learn really more from our mistakes than from the correct diagnosis we hit upon once in a while, if we only are open-minded enough to realize where our mistakes lie, and do not persist in making them again and again; and I am not in the least ashamed to confess that I have made this mistake in the beginning of the present epidemic. Needless to state, that after that I was not quite as positive in pronouncing my diagnosis on the spot, though I did not make the opposite mistake of pronouncing a case to be influenza when I was not sure but that it might be a case of measles, after all.

Or one is called to see a child with a high fever, and is told that it has been taken ill suddenly and has vomited. The child's skin shows an exanthema, consisting of small punctate erythematous spots on the chest, the abdomen, and the sides of the extremities; an inspection of the patient's pharynx reveals a considerable livid redness of the tonsils, the uvula, and the palatine arch, which is sharply bordered above. What more natural than that the diagnosis of scarlatina will suggest itself? Still one had better defer pronouncing this when in the midst of an epidemic of influenza.

Another picture: You see a little patient, a baby, who has been ill for a few days, who has now a high fever, throws itself around a great deal in bed, is very restless, cries when taken up; its head is retracted and when you try to move the head it cries out with pain; it has, furthermore, slight jerking of the extremities. Do not fail to look into the patient's ears, an examination you should never omit as part of your routine examination in young children. This may save you in this instance from making a wrong diagnosis of meningitis. In influenza you will often find a hemorrhagic inflam-

mation of the drum membrane which is bluish-red or bluish-black, and which may show either ecchymoses on its surface or still more frequently one or more bloody blisters upon its external surface. If you know what to do you will make a paracentesis at once and give the child instant relief and help it to a quick recovery, otherwise you will wait and let nature take its course until finally the pus breaks through, while the child is suffering all this time and the disease may spread into the mastoid cells. In the pus you will find the coccobacillus in large numbers.

We must, however, not forget that there is a distinct clinical picture of nervous influenza, where you can observe all degrees, from meningeal irritation, or meningism, to severe inflammations of the meninges, even purulent or parenchymatous changes. The toxic irritation causes headaches of the severest degree, and in small children stupor which may alternate with eclamptic seizures. In these cases you will find at post mortem only a slight opacity of the meninges. The true meningitis may be due either to the coccobacillus or due to secondary infection from the middle ear. Sometimes you may also see a case with hemorrhagic encephalitis or with symptoms closely simulating poliomyelitis after an attack of influenza. In all these cases lumbar puncture will be of great aid to you in making your diagnosis, and in some cases you may be rewarded by finding the specific organism in the lumbar fluid.

Nor must we forget that from six to ten per cent. of the children attacked by influenza suffer from nephritis which may be of the hemorrhagic type. One of these latter cases has recently been brought to my attention.

In other cases the respiratory organs may have to stand the brunt of the infection. We may observe a severe and dangerous pseudocroup, Concetti's "forma laryngea." In young and weakly children we may have a latent bronchopneumonia which may cause sudden death; or we may have to deal with an extensive bronchitis in the medium-sized and even the finest bronchial tubes; these are accompanied by continued fever, nervous symptoms, and somnolence which is hard to combat, or the child may be quite lethargic for some days. What may be the final result of this infection of the respiratory tract I have told you when speaking of the pathological anatomy. The dry swelling in the nose with which the disease often begins is a frequent source of nose-bleed.

So much about influenza; let us now look at the symptomatology of the grippy infections. Let us first take the case of an infant in an institution, an orphan asylum or a Baby's Hospital ward. The infant may have been getting along nicely, its stools were normal and its gain regular and sufficient, when all at once it will have diarrhea, perhaps also vomit, have some fever, and be restless; what more natural than to think of a food-intoxication, or a cholera infantum, as it used to be called, especially if the child had been suffering from severe digestive disturbances before? A few hours will tell the story; we then see the discharging nose of a typical coryza of grippy origin. But when we first approach the case, what are we to do? Are we to subject the baby to starvation, this being the only rational procedure in food-intoxication, or are we to continue the same food that we have been giving, although in slightly reduced amounts, which would be the rational procedure in a grippy infection, es-

pecially in an infant who has already been weakened by digestive disturbances and in whom even a short period of starvation might be of serious import? This, gentlemen, is one of the most difficult and momentous decisions for the physician in an institution for infants, and it will bring before one's mental eye the full responsibility he bears, though to the tyro it may seem to be easy.

In private and dispensary practice we frequently hear the following story: A young child has had what the parents call a slight cold in the head, with a running nose and some difficulty in breathing and consequently in nursing or taking the bottle; then it develops some cough, to which little attention is paid until it is brought to you or you are called in a hurry and find the baby with a severe bronchitis or a bronchopneumonia. What has happened in this case? The child contracted a coryza, which was at first in the anterior part of the nose only, whence it spread to the posterior part of the nasal cavity, then the child had a tracheolaryngitis, and this being neglected the disease followed its downward course, first into the large bronchial tubes and then still farther down until finally we see it with a fully developed bronchopneumonia, and everyone of you knows what that means.

Some children—we might say the more fortunate ones—have the symptoms of pseudocroup with their laryngotracheitis, and as this usually frightens the parents, the physician will probably then be called early enough to prevent the downward march of the infection.

How many cases of grippy infection do we see day in and day out where we stand helpless almost and where we have to say to ourselves that if we had only been called more promptly we might possibly have been able to stop the further progress of the disease?

Let us always remember that a grippy infection, even a slight coryza, if such is possible, is portentous, the more so the younger the child, and that we as careful physicians to whom the health and life of our patients is entrusted must never make light of these conditions.

I shall not go into the complications of the grippy infections, this would lead us too far, but I will mention the one which is the most frequent and at the same time one of the most dangerous, namely, otitis media. The Eustachian tube in young children is patulous and comparatively wide; what then is more natural than that the bacteria in the secretions of a posterior rhinitis should find their way into this passage, there to ascend and to cause sometimes irreparable damage? Let me state again that we must never make light of the grippy infections.

Diagnosis.—This has been largely covered in the Symptomatology, but let me recapitulate that the diagnosis of influenza is by no means easy, except at the height of an epidemic, and that even then we may mistake it for meningitis, measles, or scarlet fever, in infants for digestive disturbances, and vice versa. Sporadic cases are extremely difficult to diagnose and are undoubtedly very frequently misnamed.

The diagnosis of the grippy infections is easy from the history of the case alone, though in infants who have been suffering from digestive disturbances we may be at sea for some hours.

Prognosis.—The prognosis of influenza in children, even when the lungs are involved, is on the whole favorable, but the social condition of the pa-

tient and consequently the care that he can receive is often decisive.

In the grippy infections the age of the patient is of the greatest importance; the younger the child the more doubtful his recovery, provided we have not been called in the very beginning of the infection.

Treatment.—This part of my paper will, I am afraid, be the most disappointing to you, because I can not give you anything new, nor can I tell you of any specifics; but this does not mean that we are not able to do a great deal for the comfort of our patients nevertheless.

In influenza the therapy is mostly symptomatic. We naturally keep the child in bed even for a few days after the acute symptoms have disappeared. The diet in older children should be liquid at first, then we give a generous diet rich in proteids. Starvation must be avoided, the more so as these patients are usually suffering from anorexia. In babies we continue with the food on which the baby has been thriving, though in slightly reduced quantity, giving more water. Older children also will be very grateful for a plentiful administration of water, which may be given advantageously in the shape of lemonades, fruit juices, and ices. Hydrotherapy is of great benefit, especially in young children, but the older ones will also react very well to cold baths or packs for the high fever, and hot bath with cold effusions for the stupor.

Of drugs you may use the salicylates in small doses, or quinine; in older children, aspirin with sodium benzoate; for the irritating cough, inhalations of tincture benzoin will be soothing; in bronchitis or when the diarrhea is severe you may have to resort to an opiate; but on the whole drugs are of minor importance compared to hygienic measures. The complications must naturally be met as they arise.

For the grippy infections I resort entirely to instillations of argyrol in rhinitis, in babies especially. I also use instillations of adrenalin to facilitate the breathing through the nose, and this is also done before nursing to make this easier. For the laryngotracheitis and the bronchitis I use wet compresses and packs, and I am also a great believer in the efficiency of the bronchitis kettle or one of its substitutes, with or without the addition of turpentine or tincture of benzoin, but I do not use cresolin or formaldehyde or similar lamps, as I am convinced that it is the moisture of the atmosphere around the child that does the work and not the medication. Drugs administered internally I have given up almost entirely, except to meet complications; the results I have observed from the hypodermic administration of some of the newer remedies, have been by no means convincing.

The principal point in influenza as well as the grippy infections is prophylaxis. In epidemics of influenza children should avoid all public or private gatherings, also all public conveyances, and they should be guarded most carefully against exposure.

As to the grippy infections, especially in infants, and mainly those in institutions, I have indicated the best means of prophylaxis before, and I have only to add that if people would refrain from touching and still more from kissing children and, if we could enforce the laws against promiscuous expectorating, the number of these infections would be materially reduced.

ENTEROPTOSIS.

By F. ROBBINS, M.D.,

NEW YORK.

General Remarks.—Enteroptosis means a descent of otherwise healthy abdominal organs below their normal level, in the direction of gravity, and is characterized by abnormal mobility of the displaced viscera. The displacement may concern the bowel, the stomach, the liver, the spleen, and the kidney. The condition is named after Glénard, who regarded it as extremely common, believing it to be present in ninety or more per cent. of all persons who seek professional advice.

The cause of enteroptosis, aside from congenital factors, is referable to a lack of tonus of the anterior abdominal wall. This relaxation affects the abdominal muscles, so that the recti become insufficient and unable to resist the intraabdominal pressure. The onset of enteroptosis is favored by traumatism and violent exercise. Pregnancy, and improper clothing, such as tight corsets, are important etiological factors, and enteroptosis is accordingly more frequent in women than in men. Symptoms on the part of the uterus are often relieved by the treatment of enteroptosis. Rational methods of treatment are based upon the recognition of the etiological factor of the disease, which is relaxation with atony. Enteroptosis gives rise to a train of rather indefinite symptoms, indigestion with abdominal discomfort, increased peristalsis and constipation, nervousness, mental depression, and vertigo.

Radiography.—The extreme frequency of gastroptoses of all degrees, in women as well as in men, is best revealed by x-ray examination, which also explains the reason why conservative therapeutic measures fail in a certain number of the cases, on account of adhesions fixing the displaced stomach at various points of the abdominal cavity. Radiography illustrates the inadequacy, futility, or actual harmfulness of most of the customary procedures for the correction of the gastric displacement. A revolution of the pathology of the large intestine has been brought about by the use of the x-rays, which also afford valuable information on the subject of enteroptosis. However, the opinions of specialists are still at variance as to the interpretation of the findings. In enteroptosis, the last coils of small intestine are no longer in the vicinity of the cecum, but they have dropped down into the small pelvis. The transverse colon is usually lowered, and the hepatic flexure is often displaced downwards, while the sigmoid flexure sags more frequently than any other segment of the large intestine. The descent of the large bowel (coloptosis) is of even greater clinical significance than a sagging stomach, whereas ptosis of the small intestine is relatively unimportant.

Recent Statements of Prominent Clinicians and Operators.—The most recent important contributions to the subject of enteroptosis (splanchnoptosis) are those of Thorkild Rovsing¹ and of Grechen.² The monograph of the former, entitled, *Gastro-Coloptosis*, contains chapters devoted to the discussion of the pathological significance, which in the author's opinion is frequently underestimated, the *clinical pictures* of the disease, its diagnosis and treatment; with a report of three hundred cases treated by gastropexy. Rovsing emphasizes the numerous confusions of gastroptosis with other diseases of the stomach, such as gastric ulcer or

cancer, and the frequency of mistaken treatment. Inefficient or harmful gastroenterostomies for "suspected ulcer," as well as most useless appendectomies and oophorectomies, can be avoided by the proper recognition of enteroptosis, and its cure through the performance of an operation (gastropexy), or the application of a bandage, according to individual needs in a given case. Proper fixation compensates for the lost function of the suspensory ligaments of the stomach, and the resulting loss of normal support. The power of evacuation of the stomach is improved, as the indirect effect of the operation. Gastropexy is absolutely indicated in all those cases of gastrocoloptosis in which the patients are semi-invalids, and more or less unfit for work, on account of their gastrointestinal disturbances, in spite of systematic medicinal measures and the application of an abdominal supporting bandage. In order to be efficient in any case of enteroptosis, the bandage or binder must meet the following conditions: The pressure must act widely, on the hypogastrium alone, by means of a large strong pad or pledget; the pressure must be uninterrupted and extensive; the bandage must be so constructed that the patient can put it on in the morning, before getting up, while the abdominal organs are still in their proper place.

Enteroptosis is considered by some authors as a phenomenon of degeneration, one of many symptoms of a universal asthenia; while others believe that the displacement of the organs as such is the actual cause of most of the distressing symptoms and disturbances. Rovsing points out that there is a tendency among physicians as well as in the laity, to regard as hysterics or malingerers many unfortunate sufferers from enteroptosis, who on examination were found to be free from organic or functional disease of the digestive system. In those cases gastropexy, in his experience, has a most beneficial effect, and requires to be supplemented by gastroenterostomy, or more rarely resection, only when the condition is complicated by duodenal ulcer, pyloric stenosis, or hourglass stomach.

Grechen considers *gastroptosis* as a congenital displacement of the stomach. Well-marked cases were observed by him in children less than five years of age. The displacement is always associated with anomalies of microscopical structure, congenital weakness of the muscular layer, insufficient secretion, general relaxation, and a tendency to disease. The muscular tonus of a displaced stomach is diminished or altogether lost, and enormous quantities of indigested, half decomposed food will occasionally collect, with disastrous results, in a sluggish dilated stomach. The diagnosis of gastric dilatation—a result of gastroptosis—is based essentially upon the history, the long-standing digestive disturbances, symptoms of gastric ulcer, anorexia, obstipation, general weakness, and nervous irritability. The most favorable cases of gastroptosis are those in which the upper pole of the stomach is not much lower than the umbilicus. In very advanced cases, the displaced stomach rests upon the pubic ramus, filling most of the large pelvis. Midway cases are those in which the lowest point lies between the umbilicus and an imaginary horizontal line drawn through the two iliac crests.

Gastroptosis and *enteroptosis*, from the therapeutic point of view, are a single closely associated disease. The descent of the stomach is invariably

accompanied by intestinal disturbances, which in a number of cases govern the clinical picture. The duodenal digestion is necessarily impaired, as the direct consequence of the pathological processes in the stomach and at the pylorus. Furthermore, it results from the congenital etiology that the deficiency is never limited to a single segment of the digestive apparatus, but that the entire system is involved in the degeneration. Ptosis of the sigmoid flexure of the colon is the most common type of displacement of the large bowel. On the other hand, the duodenum is not apt to leave its normal position, although a vertical displacement of its first segment has been observed as a sequel of gastropptosis. The jejunum and ileum are so freely movable under normal conditions that enteroptosis here plays a subordinate part. Conditions differ in the large intestine, where the sigmoid flexure shows a predisposition to displacement. Motor insufficiency is the principal factor, and this is maintained and aggravated by congenital (more rarely, acquired) anomalies of position. The enteroptosis is not primarily due to abnormal mechanical pressure of a dilated stomach upon the transverse colon, but is in all probability dependent upon congenital developmental variations.

Treatment.—In a general way, surgical treatment of gastropptosis is reserved for the gravest cases, whereas all other patients are treated only with dietetic and internal measures. Although these can hardly accomplish a cure, the disturbances may be efficiently controlled and the nutrition greatly improved, so that operative interference no longer enters into consideration. A purely vegetable diet, including egg-yolks, is usually recommended, with restriction of all sorts of fluids, not excepting milk, unless this be incorporated in the solid dishes. One-quarter to one-third of a liter is sufficient beverage for the day. In this way, the dilatation of the gastric wall and irritation of the mucosa may be prevented, or at least essentially diminished, most of the digestive work being done by the salivary glands, the pancreas, the bile, and the enteric juice. Routine washing of the stomach in these cases is now entirely abandoned, as the few remnants of active gastric juice are swept away by the irrigations. Regulation of the bowels is of the greatest importance in all cases of displacement of the stomach alone or together with the intestine.

The *treatment* of enteroptosis is based upon the symptoms and must meet the double indication of disinfecting the intestinal contents and regularly emptying the bowel. Relief is often secured by well-adjusted supporting bandages, properly selected exercises (for strengthening the abdominal coverings), cold baths, electricity, and massage. Surgery, in form of the application of an anastomosis between the lowest point of the stomach and the highest jejunal coil, is regarded by Grechen as the simplest and most reliable radical treatment, in severe cases of chronic enteroptosis. This operation has highly beneficial results, and owing to the improved modern technique, its mortality (10 per cent.) would be still lower, if surgical intervention were not often too long delayed. Other procedures, such as pylorotomy, or plastic dilatation of the pylorus, are either inefficient or too dangerous. The indications for surgical interference are restricted to the advanced cases of enteroptosis, unrelieved by symptomatic measures, in which the dilated paralyzed stomach and displaced intestines have led to

severe digestive disturbances, notably vomiting, loss of weight and nervous symptoms.

The importance of careful individualization in these cases is emphasized by Ransohoff,⁸ who states that even desperate cases of enteroptosis with grave neurasthenic symptoms, are often permanently cured by operation, which should not be too long delayed, after all other measures have been found inefficient. However, only those cases of gastropptosis should be operated upon in which a serious functional disturbance, amenable to surgical relief, is present. Goldthwait⁹ emphasizes the importance in these cases of "teamwork" between the physician, the surgeon and the orthopedist.

A good description of enteroptosis and splanchnoptosis is given by S. Goodwin Gant,¹¹ who states that this condition may be general (Glénard's disease), when the liver, kidneys, spleen, stomach and intestines descend below their normal level; or localized, when the displacement concerns but a single organ or section of an organ, as for instance when there is a sagging of some particular part of the large intestine. Enteroptosis is sometimes due to a separation of the recti muscles, and ingenious procedures have been devised for the repair of the abdominal wall. The first treatment recommended for the support of displaced organs was Glénard's elastic hypogastric belt. This has been more or less successfully imitated by many mechanical devices, in form of belts, trusses, stocks, girdles, binders, pressure-pads or pledgets, plaster jackets, corsets and roller bandages. Gant points out that these supports should conform to the lines of the body while breathing, walking and defecating, but must also be sufficiently firm to retain the displaced organs in position, at all times. A support of this kind must be worn for weeks or months. Systematic deep breathing, massage, and mechanical vibration, as well as electricity and hydrotherapy, are useful adjuvants in the treatment of enteroptosis. After the failure of non-operative measures, surgical procedures are indicated for the restoration of the displaced organs and their fixation in, or as near their normal position as possible. The fixation of the displaced colon to the abdominal wall (colopexy and sigmoidopexy) have proved successful measures in the treatment of enteroptosis in the experience of Gant, who has devised several modifications of the operative technique, especially for the management of sagging portions of the bowel after it has been fixed to the abdominal wall. His experience with colopexy, which he does not regard as a dangerous operation, has convinced him that persons suffering from obstipation and other troublesome manifestations of enteroptosis, who fail to obtain relief from non-surgical measures, can in many instances be permanently cured by this procedure.

Based on his assumption of congenital relaxation of all tissues, in enteroptosis, Zweig⁹ is not in favor of surgery in these cases. Although the stomach, the colon, or the kidney, as the case may be, can be anchored in place, this will not alter the clinical picture of visceral neurosis, the anatomical dislocation of the organs being relatively unimportant as compared to the symptoms on the part of the digestive and nervous system. Rational treatment aims at restoring the mechanical equilibrium in the abdominal cavity, thus counteracting the further descent of the viscera; and also at relieving the associated disturbance of the digestive nerve-system.

Gastroptosis being in the great majority of the cases the more or less remote result of gastric atony (Gazaignaire⁶), the displacement may be relieved by dietetic measures, after the normal shape and position of the stomach have been re-established, and the kink in the pyloroduodenal canal has been straightened out. Belts, bandages, and other abdominal supports aim at this result. The effects obtained depend not so much upon the displacement itself, as upon the configuration of the abdominal walls. When the patient's abdomen is relaxed and hangs down, the results are often excellent, whereas in the case of a flat and caved-in abdomen, treatment of this kind is apt to prove unsatisfactory. A stomach not bound down by adhesions is usually well held up by a non-elastic belt, with a pneumatic fixture. The elevated organ tends to resume its normal shape, and promptly responds to the beneficial effects of restitution and dietetic régime. The advantages of this method of treatment consist in the often immediate relief of the painful symptoms; the relatively rapid gain in weight; and the definite return of the stomach to its normal position, the required time depending upon the degree of gastric atony present.

The existence of gastroptosis cannot be surmised on the basis of the subjective symptoms complained of by the patient, for in the great majority of the cases, the symptoms do not differ markedly from those of atony of the stomach, or hypasthenic dyspepsia. Gastroptosis finds its clinical expression in the disturbance of the rhythmic evacuation of the stomach. This delayed emptying of the organ is dependent upon the two factors of motor insufficiency (gastric atony), and obstruction of the digestive passage through the resulting curvature in the pyloroduodenal canal. The displacement of the stomach is revealed through the routine examination of the gastric boundaries, and the demonstration of a lowered inferior margin and lesser curvature. Simple percussion will not suffice to show the descent of the lesser curvature, when ptosis and atony are associated with dilatation, as is frequently the case.

Based upon the observation that in certain cases of enteroptosis the disturbances are not so marked when the bowel is full, as the result of several days' constipation, Arnoldi¹² recommends an abdominal support which is held tightly in place by a roller bandage directly above the symphysis. This bandage does not aim at retaining the stomach and the bowel, but at preventing the descent of the upper abdominal organs, through the firm fixation of the lower organs. Lerch, who points out that the intra-abdominal pressure must be restored in these cases, has devised a suitable whale-boned cloth bandage, which restores the pendulous abdomen to the normal, or nearly so. A natural belt, strong enough to resist the intra-abdominal pressure, can sometimes be provided by surgical interference, after medical and orthopedic measures have been exhausted. Resection of a portion of the relaxed abdominal coverings serves to tighten the wall, and may be sufficient to keep in place, without anchorage, the dislocated organ or organs. (Lamyot de la Haye.)

Displacements of the *liver* and the *spleen*, hepatoptosis and splenoptosis, are observed only in cases of very marked tissue-relaxation, congenital or acquired. The condition is usually noted in those cases in which a pendulous abdomen, with all its sequelæ, develops as the result of acquired me-

chanical factors (such as difficult childbirth, or surgical extirpation of very large abdominal tumors). The same causes may also lead to a displacement of the *kidney*, known as nephroptosis. The symptoms are usually vague, and partly referable to nervous irritability or weakness. A displaced pelvic kidney is usually congenital, and may never give rise to disturbances of any kind, but cases have been recorded in which it has acted as a serious obstacle to childbirth. The symptoms of renal displacement consist in abdominal pains, digestive disturbances, and nervous affections of variable degree. No operative interference is called for, unless the symptoms are of considerable severity. Removal of diseased female genital organs leads in many cases to subsidence of the renal symptoms. (Plummer.³) The indications for operative interference with the kidney itself must be based upon the anatomical degree of the displacement, the gravity of the condition, especially strangulation, and the presence of complications, such as intermittent hydronephrosis, pyelonephritis and nephritis. The operation of choice for pelvic and otherwise displaced kidneys is dislocation and reimplantation in a place where the organ will not be a mechanical hindrance. Provided the necessary precautions are observed, the anchorage of the kidney is usually followed by very satisfactory permanent results.

A complete discussion of enteroptosis should include the mention of displacements of the esophagus and of the heart (cardioptosis), although these ptoses are not common. Ptosis of the female genital organs (prolapse) is a condition of itself, and is not usually included under the general heading of enteroptosis.

11 WEST FORTY-FIFTH STREET.

Appendicular Abscess in an Infant.—Phélip records a case in a child, aged thirteen months, bottle-fed, who had suffered from constipation for two months. The symptoms were fever, diarrhea, blood in the stools, and a swelling in the right iliac fossa. Laparotomy was performed, and an appendicular abscess was found. Recovery was complete.—*Brit. Journ. Child. Diseases*.

THERAPEUTIC ACTION OF CARBONIC ACID BRINE BATHS (NAUHEIM BATHS) IN CARDIOVASCULAR DISEASES.*

By JAMES HENRY HONAN, M.D.,

BAD-NAUHEIM, GERMANY, AND AUGUSTA, GA.

FOR the past seven years I have given much study to the clinical effects of CO₂ brine baths, studying cases at a European spa, Bad-Nauheim, accompanying patients to the bath, observing the effects on patients during immersion, as well as after the bath, studying the different forms of cardiovascular disease and the effects of the baths in each, keeping a close record of each case, noticing and comparing the effects on many of the patients for a number of successive years.

For the past four years in this country, I have studied in my winter practice in the South the clinical effects of the baths, made from the Nauheim salts and prescribed and administered with the same care, variation and watchfulness which I have found so important in the treatment of my patients at the European spa.

The observations and records which I have made here at home and those made in my practice abroad lead me to the conclusion that just as favorable results can be obtained in America, and every year has given me a broader and firmer faith in CO₂ brine baths as a therapeutic measure.

There is, in our country, a tendency to overestimate the effect of the CO₂ gas, attributing almost entirely to this element of the bath the hyperemia and other desired effects. It is true that the chemical action of the gas bubbles on the nerve ends of the skin increases the dilatation of the capillaries, lessens the peripheral resistance, and reduces the endovascular pressure. Laquer, Solmsen, and others, however, have emphasized the greater importance of the *salts* of the bath in producing the physiological effect, and my own observations corroborate their tests. I have frequently observed as much hyperemia of the skin in the "Thermal bath" in which there is no free CO₂ gas.

It is my experience, as well as that of my colleagues at the Nauheim spa, that certain cases make more satisfactory improvement from a course of baths consisting entirely of thermal or brine baths, in which there is no free CO₂ gas, than from a course in which Sprudel baths, a supersaturated solution of CO₂, have a place. The great importance of the temperature of the bath and the variation of temperature for the individual through the course of treatment, I have dwelt upon at length in previous papers.

The majority of baths I prescribe at the neutral zone of temperature, that is, between 32° and 34° C., giving the cold bath only where there exists a subnormal endovascular pressure with a flaccid, toneless arterial wall.

A cold bath with the sudden constriction of the peripheral capillaries and of the arterioles, and the greater amount of blood forced into the renal circulation, may cause much mischief to the kidneys. Cold baths should be prescribed with great caution, and particular vigilance should be kept on the urinary output. Care should be exercised that no irreparable damage be done to the kidneys, while trying to improve the heart and blood-vessels. The shock occasioned by the sudden very cold bath is,

in my opinion, pernicious, notwithstanding that it causes a temporary stimulation and feeling of well-being. The insidious effects are often met with much later in the renal or pulmonary circulations. I do not believe in the shock, excepting in very extreme emergency cases.

The CO₂ brine bath has a mechanical and chemical action which is peculiar to this kind of bath, while the temperature action which is common to all baths may be employed with these baths to increase or decrease the mechanical or chemical effect. The mechanical and chemical irritation of the skin produced by these baths induces a sense of heat which neutralizes the temperature of the water, admitting of a wider range of neutral temperature than in a plain bath.

In consequence of the mechanical and chemical irritation of the skin there is a marked hyperemia, an increased activity of peripheral capillaries, and an increase of the peripheral blood space, with the resultant unburdening of the overtaxed or weakened heart.

The slowing of the pulse is a constant action of these baths and is most important. The slowing, as shown by a large number of sphygmographs, is due to the lengthened diastole. This lengthening of the compensatory pause permits of a more complete filling of the coronary arteries, an increased activity in coronary circulation; thereby adding to the integrity of the myocardium, improving the metabolism in the myocardial tissue, and increasing the force of the systole—all of which show that the CO₂ brine bath does not add extra work to the heart, but improves that organ and relieves it of the extra burden.

The increased length of the compensatory pause, with a more nearly complete filling of the ventricle and a more nearly normal systole, leads to greater pulse amplitude. With more time for the ventricle to fill there is more time for the muscle to recover from fatigue, so that the systolic output is increased. The heart requires sufficient time between beats to overcome fatigue and maintain its functional integrity. This is best accomplished by the CO₂ brine bath treatment, which produces the effect, not by the depression of the cardiac nerve supply, but in the most natural way.

The slowing of the heart rate is very important, since the heart rests only in diastole. The slowing lengthens the diastole or compensatory pause, and presses the blood more thoroughly out of the myocardial tissues, making systole more nearly complete and allowing a larger volume of fresh blood to be carried through the myocardial circulation. The increased nutrition supply to the myocardium, in consequence of the improved circulation, is soon manifest by a greater force in the systole. This increase in the coronary circulation, thus brought about in many cases of chronic myocarditis, leads to splendid results,—a permanent strengthening of the myocardium, and an improved general circulation with an improvement in the functioning powers of all the organs.

As I have stated on former occasions, though there may be a slight temporary increase in endovascular pressure in some high blood pressure cases, the increase does not put an added strain on the heart, as the heart and vessels with added energy are in much better condition to meet and overcome the change.

It has sometimes been contended that the CO₂ brine baths increase blood pressure. This effect

*Read by invitation of the Society and the Director of the Reservation Commission at a meeting of the Saratoga Springs (N. Y.) Medical Society, Oct. 21, 1915.

can occur only when the temperature of the bath is reduced below that indicated for the patient. When the baths are administered within the neutral zone of temperature from 33° to 34° C. (92°-94° F.) there is little or no rise in blood pressure, and where a slight rise occurs, it is but temporary; that is, it lasts only a few days, after the course of baths is finished, or until the readjustment of the circulation after the immediate effect of the baths is over. In the great majority of cases the effect of the baths is to reduce the blood pressure, and this effect is observed from the early part of the course.

The therapeutic effects of the CO₂ brine baths are produced by the following physiological actions: the slowing of the pulse, the increase of the pulse volume, the changing of the splanchnic blood current to the peripheral circulation and thus relieving the embarrassed heart, the increase of elimination and the consequent improvement of the integrity of the myocardium, and the increased coronary circulation. During the time these changes which equalize the general circulation are taking place, a high blood pressure may be reduced or a low blood pressure may be raised, depending on whether the endovascular pressure was too high or too low before the treatment began. The tendency of the treatment is to bring the blood pressure to the normal level.

When there is an insufficient blood supply to the central nervous system, there is observed an impairment of the general circulation. All the organs suffer from this impairment, and first and above all others the heart, from the weakening of whose functional integrity a vicious circle is formed which, if not soon corrected, leads to fatal results.

About ten years ago Ottfried Müller proved the law of antagonism or the equalization between the peripheral and splanchnic systems, that as one system is restricted there is a reciprocal dilatation in the other. I have found that the patients under my care, the majority of whom suffer from an engorged splanchnic circulation with stasis of the abdominal viscera, can best be relieved by the CO₂ brine baths at the neutral zone of temperature. The most frequent and important action of the CO₂ brine baths is elimination and the equalization of the circulation of the peripheral, splanchnic, and pulmonary systems.

Many patients who consult the heart specialist suffer from some form of circulatory disturbance. No doubt many troubles which masquerade under the name of gastric or liver diseases are primarily circulatory disorders. When we have learned more about blood pressure, how to recognize it in its incipency, to trace its early causes and give them their proper significance, we will be better able to check the increase in numbers of circulatory diseases.

There is decided evidence that a change of blood current from the splanchnic to the peripheral system of the patient relieves the engorgement of the organs of the abdominal cavity, and thus brings about a marked change in the general condition of the patient. This change is first noticed in the patient's feeling lighter on his feet and his having a keener desire to take active exercise, in the greater activity of the bowels—more copious stools and greater regularity of movement, and in the greater activity of the kidneys—a marked increase in the output with a corresponding increase in the solid constituents.

This change in circulation is a characteristic effect of the baths, and with its resultant benefits may be relied on when the baths are properly administered. There is usually an accompanying slowing of the pulse rate while the patient is in the bath, and for some time after his leaving the tub an increase in pulse volume which may continue for several hours as the result of this slowing.

The blood pressure may be acted upon more directly by the raising or the lowering of the temperature of the bath. The careful study of these immediate and indirect effects and how they are produced gives convincing evidence that the baths may be modified in such a way as to benefit a great variety of cardiovascular cases.

Endocardial and myocardial troubles are so closely associated symptomatically that it is difficult at times to differentiate them. Many of these troubles are due to a direct or antecedent infection. The observations of Billings, Poynton, Schottmueller, Paine, and Rosenow, show how often endocardial and myocardial troubles may be traced to the invasion of the viridans group. The staphylococci and other bacteria may also cause endocarditis. Endocarditis may be secondary to tonsillitis, pyorrhea, or foci of infection in other parts. It is but recently that we have recognized what a very prominent rôle lues plays in causing heart diseases.

We must in these cases, as in all cases of chronic heart disease, take a very careful case history, and where lues is suspected have a Wassermann test made. If a positive reaction is given, salvarsan should be administered, preferably before the bath treatment is begun. The CO₂ brine bath treatment in lues is not curative without salvarsan or other specifics, but I have seen much improvement follow in cases where no specific remedies had been used.

Toxemia due to high living, often in the form of overeating or malassimilation, is accountable for a large percentage of cardiovascular troubles in the well-to-do men of fifty years or over. I know of no other form of treatment which so quickly clears up these troubles as the CO₂ brine baths. The active elimination caused by these baths promotes the expulsion of poisonous products from the system, whether these products are due to a direct invasion, or the result of some acute disease, or the more chronic and much more common result of errors of diet. A careful study of these etiological factors shows us why a closely regulated diet, carefully prescribed exercise, and rest, are so often a necessary accompaniment of the baths.

One of the early effects of the CO₂ brine bath treatment in cases of chronic myocarditis is an increased diuresis. When the integrity of the heart muscle is impaired there is a decrease in urine output. This functional impairment of the kidneys is more marked during the day, the night urine often being in excess. The baths unburden the embarrassed heart, and increase its functional activity, as noticeable in hydremia and increased diuresis with reduction of edema, if present, and relief of dyspnea.

Cardiac hypertrophy is frequently due to defective valves, and arterial resistance or obstruction in the pulmonary or general circulation. The resistance is due to a hyperplastic infiltration in the arterial walls, reaching the endothelium and constricting the lumen of the vessels. The hypertrophy may become pathological if the resistance is great or long continued.

Dilatation is the result of hypertrophy or of a weakened myocardium from other causes. Passive dilatation may also occur from valvular defect or sudden strain, without hypertrophy. If the dilatation is acute absolute rest is the treatment, while the after effects due to an impaired circulation may be much improved by the CO₂ brine baths.

From a clinical point of view, it is very important that we differentiate between simple and complicated high blood pressure. Simple or uncomplicated hyperpiesis is usually transient, due to some mental strain or worry manifested in marked hypertension, with a corresponding high blood pressure reading and other subjective symptoms. The increased elimination due to the baths, the enforced rest and muscular relaxation prescribed, the quiet and changed surroundings, bring about for the majority of patients a complete and speedy recovery.

The complicated form of hyperpiesis is much more difficult to recognize, being very insidious in development and its symptoms less marked. In the great majority of cases of sclerosis of the kidney I find an irregular variation in the blood-pressure readings, which are reduced less by absolute rest than in hyperpiesis simplex, while a heavy meal causes a greater pressure increase. The polyuria and cardiac hypertrophy, while aiding the diagnosis, tend to keep the kidney function approximately normal. In these cases the high blood pressure is compensatory and should be reduced very cautiously. As previously mentioned, many of these cases under my care are due to faulty metabolism, caused by errors in diet, and therefore it is obvious that a restricted diet is an important factor in aiding the balneological treatment. In restricting the quantity of food and drink the physician must see that the patient has sufficient food to maintain the body energy. Close vigilance is necessary to avoid such exercise as may overtax the blood-vessels and cause a cerebral hemorrhage.

The baths in these cases must be administered cautiously, the bowels and kidneys kept active. Although cases of this class require very close watching, the results of balneological treatment are quite as satisfactory as in cases of uncomplicated high blood pressure and well repay the great care exercised.

The desideratum in the treatment of these cases is cardiac rest, especially in the advanced stages, when the heart should be relieved of every possible burden. The blood-pressure level which a patient may sustain in safety depends entirely on the integrity of the myocardium and the walls of the arteries. Although we agree with Janeway's opinion that the patient whose blood pressure is sustained above 200 mm. is in danger of death by uremia or apoplexy, as numerous records show, it should be borne in mind that practitioners know by experience of many persons whose endovascular pressure has remained above this point for years.

I recently reported some cases with blood pressure sustained from 202 to 240 mm. Hg. One of these patients is a man in politics and much before the public. When he consulted me first in December, 1912, in Augusta, Ga., he brought from his physician the report to me that the patient had passed through a successful campaign some months previously sustaining a blood pressure of 222 mm. I found a blood pressure of 282 mm. Hg., and the patient suffering from all the head and gastric

symptoms of hyperpiesis. The course of CO₂ brine baths which I gave him that winter reduced the endovascular pressure to 240, with a complete relief of all the symptoms, enabling him to walk at a slow gait with comfort.

In August, 1913, the patient came to Bad-Nauheim for another course of treatment, which further reduced his blood pressure. A report from him recently, two years after treatment, shows a sustained blood pressure of 202 mm. Hg. and that he is feeling quite well, although he has again passed through a rather trying but successful campaign.

It is astounding in some cases to observe the ability of the myocardium to withstand undue strain for years before the inevitable break comes. My added years of experience but confirm what I have long thought—that all these blood pressure patients should be considered heart patients, as they are sure to become such sooner or later.

Drugging measures for the permanent reduction of endovascular pressure have proved practically useless as far as I have been able to observe. Their effects are evanescent, which makes them nothing more than temporary measures.

The most rational method of obtaining a permanent gain in these cases of hyperpiesis is to make a careful study of each individual and to regulate his life accordingly, that is, his diet, elimination, sleep, rest, exercise, relaxation, and general habits. These regulations promote the stability of the beneficial results of the CO₂ brine baths. The increased elimination due to the baths equalizes the circulation and thus relieves the cardiovascular strain and brings about a marked permanent gain.

A very important evidence of the beneficial effects derived from the proper administration of the CO₂ brine baths in cases of arrhythmia is the decrease in pulse deficit, more marked in instances of auricular fibrillations and auricular flutter. It is not infrequent in the balneological treatment of these cases to observe the heart contraction return to normal rhythm.

In paroxysmal tachycardia, the effects of baths are quite marked, often producing a permanent benefit. In sinus arrhythmia as well as in heart block, where drug therapy has failed, I have observed a decided improvement from the careful administration of the CO₂ brine baths—the slowing down of the heart to a normal rhythm and improvement in the general condition of the patient.

When there is an intermittent pulse or when ectopic beats or extra systole are present and the heart is overburdened, the treatment often gives very gratifying results.

Auricular flutter and auricular fibrillation are indices of myocardial impairment, and by their excitation add an increased embarrassment to the heart action. Therefore, they should be considered as serious conditions, though occasionally a patient with auricular fibrillation may live for years. Pulsus alternans is found only where there is a positive damage to the contracting power of the heart and is more ominous in character.

The frequent association of all these irregularities of the heart, with serious changes in the atrioventricular bundle of His or its branches, usually indicates a grave prognosis, although these conditions are not absolutely incompatible with long life.

Among a number of such cases under my care, the two following may be taken as typical: The

first is a man of sixty-six years, who has had an irregular pulse for twenty-five years. He conducts a large business, plays golf, and does most of the things which men of his age can do, without any apparent cardiac embarrassment. The second is a lady sixty-one years old who five years ago had a severe acute endocarditis and has since had a marked irregularity of the neurotic type. Though this patient is very much restricted in her physical exercise and it requires constant care to keep the heart action at compensation level, she suffers no further discomfort. She is now able to walk 1,300 to 1,800 feet on the level without discomfort or ill effects. The normal pulse beats are much more numerous, the imperfect beats less frequent. The latter can be counted only by the stethoscope. The pulse deficit is becoming gradually less as the myocardial integrity improves. In the last five years the former of these patients has had two courses, and the other four courses of baths.

The circulation is so exquisitely balanced and so nicely adjusted to all the organs of the body that the slightest deviation in one organ may cause a derangement in all the organs. If the force or pressure in one is increased, a relative change may extend to all. When there is present hyperplastic infiltration of the arterial walls causing a primary blood pressure, all the abdominal viscera soon become involved, the entire splanchnic system becomes engorged, and the patient soon presents the picture of cardiac insufficiency with all the manifestations of broken compensation.

If treatment in these cases is begun before irreparable changes have taken place in the myocardium, the process can be arrested and much improvement of the condition brought about by means of CO₂ brine baths. The increased peripheral circulation caused by the baths relieves the engorgement of the abdominal viscera and re-establishes metabolism, with the result of general improvement. Numerous instruments of precision have been devised which have aided much in our diagnosis. Indeed there is no part of internal medicine that has progressed so rapidly as our knowledge of cardiovascular diseases—making possible much earlier diagnosis and treatment, with consequent lessened mortality.

The CO₂ brine bath has now established its great value as a conservative therapeutic measure in almost all forms of subacute and chronic cardiovascular diseases. Conservative practitioners have observed such a marked and permanent improvement in their patients after the balneological treatment that there is a growing confidence in this form of treatment which only a reliable and safe method can inspire. Every year the tendency to place less confidence in drugs is more pronounced. The use of strychnine is now almost or entirely abandoned in these cases by many practitioners. Digitalis has been much more restricted in its range of administration, although it is now about the only drug used exhibiting any degree of satisfactory results. Clinical studies of the effects of drugs have been disappointing and, aside from the vasodilators used in anginoid pain and digitalis in selected cases, few other drugs are of use.

The nonreliability of drugs in cardiovascular diseases has directed the attention of medical men more to the efficiency of the CO₂ brine baths in these cases and has caused them to study more carefully balneotherapy, and also to give more importance to rest, diet, and heart gymnastics.

As a result of scientific observations, there has accumulated a large amount of data concerning the physiological action of CO₂ brine baths. These observations prove beyond peradventure the unvaried physiological action of these baths and should remove all doubt of their efficacy in cardiovascular diseases. There are convincing proofs that we have in the CO₂ brine bath a therapeutic measure of the highest value, one that admits of the finest gradations in administration, and a variation in application impossible in any other therapeutic measure. The greater permanence and reliability of the effects of these baths begets for them a confidence which drug therapy does not have.

The action of the CO₂ brine bath has often been compared to the action of digitalis on the heart. Digitalis slows the pulse by impeding the conduction of the impulses through the atrioventricular bundle of His. The bath slows the heart action, but without impeding any function. The slowing is brought about by relieving the burden of the toxic and overdriven heart, by direct action on the myocardium, by improving the coronary circulation. The lengthened diastole causes a more vigorous contraction and a complete pressing out of all the stagnant blood in the myocardial tissue, thus slowing and strengthening the heart in the most natural way, with the results plainly shown of a better general circulation and longer lasting benefits to the health of the patient.

The CO₂ brine bath affords us a reliable therapeutic measure in nearly all forms of chronic cardiovascular diseases, as the most natural stimulation to the heart and vasomotor system. As an active agent in producing general elimination, in equalizing an impaired circulation, in the correction of blood pressure, in arresting tissue change, there is no other therapeutic measure so reliable. The invariable action of the baths and their safety, when administered as indicated, give them a place in therapeutics which is becoming more and more apparent.

The change of attitude of prominent medical men who were long skeptical, and rightly so, until they were thoroughly convinced, is more and more noticeable every year, and every year adds to the list of names of those foremost in the rank of internal medicine who recommend the CO₂ brine bath treatment for their patients.

936 HICKMAN ROAD.

VITALITY OF THE CHOLERA VIBRIO IN THE WATER OF NEW YORK BAY.

By A. J. GELARIE, M.D.,

ROSEBANK, N. Y.

(From the Quarantine Laboratory, Port of New York.)

WHILE sporadic cases of infectious diseases, like typhoid and cholera, are ordinarily transmitted by personal contact of individuals, epidemics are, as a rule, caused by polluted water, whatever its use, whether it be for drinking or washing purposes or otherwise. According to Schueder (*Zeitschr. f. Hyg. and Infkr.*, Bd. 38, S. 343, 1901) about 70 per cent. of all epidemics are caused in the manner aforementioned.

An examination of the waters in and about New York Bay is therefore of the utmost importance, inasmuch as there are usually a large number of vessels at anchor in New York Bay and vicinity. Such vessels may at any time come from countries

where cholera is prevalent. Notwithstanding the short duration of the disease, it is well known that even convalescents may contain cholera vibrios in their dejecta as much as 48 days subsequent to recovery. When, as is usual, dejecta are thrown into the bay, danger is imminent.

With such obvious dangers in mind, Health Officer Dr. Joseph J. O'Connell raised the question as to whether or not the cholera vibrio would die or survive if placed in the water of New York Bay off the Quarantine Station. This water is a mixture of Hudson River water and sea water in proportions varying with the tides. If cholera feces should pass from an infected ship into this water, would the cholera vibrios die immediately, or survive a few days only with little or no multiplication, or would they survive and undergo a progressive multiplication? Without question in the latter instance there would be a practical danger of contamination of such water from ships with cholera cases on board. If, however, the vibrios merely survive a few days without any multiplication, infection, although improbable on account of the great dilution of the feces in such a large body of water as New York Bay, should be guarded against.

Two factors should be considered as to the survival of cholera vibrios in such water; first, the sudden increase in osmotic pressure due to the large amount of salt in the water, and secondly, the overgrowth of the cholera vibrio by other organisms present in the water. A strain of cholera that had been isolated a few months previously in the Philippine Islands was employed in the experiment.

To study the influence of the first factor, water was collected in a large sterile flask near the center of the bay and was heated in the autoclave for 20 minutes. The sterilized water was then inoculated with cholera from an 18-hour agar slant and plated at once to determine the number of cholera vibrios present. Similar platings were made at from 24 to 48 hour intervals; the results of this are shown in Table I.

TABLE I VIABILITY OF CHOLERA VIBRIOS (MANILA STRAIN) IN STERILIZED BAY WATER
Number of cholera vibrios per cubic centimeter=

At once,	7,280	After 7 days, 1,600,000	After 16 days, 250,000
After 24 hrs.,	22,800	After 8 days, 1,648,000	After 17 days, 236,000
After 48 hrs.,	131,600	After 9 days, 672,000	After 19 days, 255,000
After 3 days,	674,000	After 10 days, 500,000	After 20 days, 180,000
After 4 days,	1,216,000	After 11 days, 800,000	After 21 days, 200,000
After 5 days,	1,620,000	After 12 days, 554,000	After 24 days, 240,000
After 6 days,	1,280,000	After 14 days, 305,000	After 26 days, 328,000
		After 15 days, 292,000	

As can be seen from Table I, there is a constant increase at the outset, lasting for about eight days, followed by a gradual decrease lasting for about fourteen days. This, however, will be hereinafter discussed.

Having shown that the subjection of the cholera vibrios to sudden increase in osmotic pressure has no apparent effect on them, it was then planned to study the influence of the associated microorganisms in the unsterilized water of the bay. Water was collected from near the center of the bay off Quarantine, as heretofore, and was at once inoculated with cholera from a 24-hour agar culture (great care, however, being taken not to transmit any nourishing material from the culture) and at once inoculated on Dieudonné's medium and other specially prepared differential media in the manner described below:

A given number of loops were inoculated on the plates and the resulting colonies counted after incu-

bation for from 24 to 48 hours. The specially prepared plates have been worked out by Drs. Teague and Travis and will be fully described by them in a later article. These plates are very suitable for differentiating cholera colonies from other colonies by virtue of their color. In this way the cholera and non-cholera colonies could be counted. In addition agglutination tests have always been made. The results are detailed in Table II.

TABLE II UNSTERILIZED BAY WATER INOCULATED WITH CHOLERA VIBRIOS

	Cholera Colonies	Other Colonies		Cholera Colonies	Other Colonies
At once	270	2	After 4 days	0	6
After 24 hrs.	9	2	After 5 days	0	10
After 48 hours	0	1	After 6 days	0	15
After 3 days	0	1	After 7 days	0	60

Table II shows that the number of the cholera vibrios in the native bay water decreases rapidly while the other colonies increase in number. The experiments detailed below extend over much longer periods and the presence of viable cholera vibrios was determined by enrichment in peptone water. Different strains of cholera were used in the different experiments.

The method employed was similar in nature to that described above. To 200 c.c. of water contained in an Erlenmeyer's flask a certain amount of a cholera suspension was added, great care, however, being taken not to transmit any nourishing material from the culture. The flasks were kept at room temperature and in the dark. At intervals, as set forth in the tables below, a certain amount of the water was plated, and the number of the colonies developed thereon counted. To the water remaining in the flask a given amount of peptone was added, so as to make up a 1 per cent. solution (Anreicherung). After from 16 to 18 hours' incubation plates were made from the peptone on ordinary alkaline agar and also on Dieudonné's medium. The characteristic colonies, as well as those which appeared suspicious, were fished, inoculated upon agar slants, and then subjected to the agglutination test. In some cases, where there was any doubt, the colonies were again transferred to peptone for a period of 48 hours and then again to agar.

The growth which takes place on Dieudonné's medium has never been relied upon as a conclusive test for cholera, since it has been found that other microorganisms, like the *Bacillus pyocyaneus*, some water bacteria, and different kinds of cocci will also grow on this medium. Hence agglutination tests were also applied to those microorganisms which had been developed on Dieudonné's medium.

Four strains were employed, one of which was an old laboratory strain which had been cultivated in the laboratory for two years; the second strain was received from the Museum of Natural History of New York. The remaining two strains were obtained direct from Egypt and Austria respectively. In general, the vibrios had been passed one or more times through a guinea pig before being employed in these experiments. Only a 16 to 18 hour culture was used.

Table III exhibits the results of an examination of the bay water, both sterilized and native, and also of the tap water taken from Staten Island. In connection with this experiment the laboratory strain was employed.

Native bay water	+	+	+	+	+	+	+	+	+	+	+	+	+	+

A review of the foregoing tables will show that the cholera vibrios lived in the native bay water for from 7 to 47 days, and in the sterilized bay water the vibrios at the expiration of 285 days are still alive, with the exception of those mentioned in Table III, which lived for a period of only 154 days, whereas in the native tap water they remained alive for only from 1 to 3 days, and in the sterile tap water from 1 to 18 days. These great differences are due to several factors, such as the strain of cholera employed, the character of the water itself, and the quantity of bacteria put into the water.

In confirmation of the foregoing statement, at-

tention need only be called to Table VII, showing the strain employed, the nature of the water, the number of bacteria added, and the period of time they lived therein.

TABLE VII—COMPARATIVE VIABILITY OF VARIOUS STRAINS

Strain	Nature of the Water	Period of Time They Lived	
		Number of Vibrios Added	
Laboratory strain A	Sterile bay water	149,500	154 days
	Native bay water	149,500	21 days
	Sterile tap water, Staten Island	149,500	18 days
	Native tap water, Staten Island	149,500	3 days
B Museum Natural History	Sterile bay water	4,000,000	285 days, still living
	Native bay water	4,000,000	7 days
	Sterile ocean water	4,000,000	285 days, still living
	Native ocean water	4,000,000	7 days
	Sterile tap water, Brooklyn	4,000,000	1 day
Egypt	Sterile bay water	60,000,000	190 days, still living
	Native bay water		47 days

In the sterile bay water containing 149,500 vibrios, they lived 154 days; in the native bay water, containing the same amount, they lived only 21 days; whereas in sterile tap water the period of life was only 18 days, and in native tap water 3 days. A different result was obtained when using a quantity of 4 million vibrios. In this connection we find that at the end of 285 days the vibrios are still alive in sterile bay water and ocean water respectively, while in the native bay and ocean water respectively they lived only 7 days. Further proof of this may be had when 60 million vibrios were added, in which case they survived for 47 days in the native bay water. The results so obtained tend to confirm the conclusion that the longevity is dependent upon the strain employed, the nature of the water, and the quantity of bacteria involved in the experiment. It goes without saying that the life of the vibrios in the sterile bay water is due to the total destruction of the saprophytic bacteria present in the water during the process of sterilization. The presence of a large quantity of nourishing material, chiefly mineral salts, is conducive to their growth. In the bay water at high tide, the total amount of solids found was 29.68060 per liter and in the bay water at low tide 28.5140 per liter, whereas the ocean water was found to contain 27.3473 grams per liter.

In the native water, on the other hand, containing the same nourishing material, their life is short, inasmuch as the vibrios have to compete with the water bacteria. No doubt, retrogressive metabolic products of the saprophytic bacteria act unfavorably upon the vibrios.

TABLE VIII—COMPARATIVE VIABILITY OF COLON BACILLI AND CHOLERA VIBRIO

Nature of the Water	Number of Bac. Coli. Comm.	Number of Cholera Vibrios	PERIOD OF LIFE OF	
			Bac. Coli. Comm.	Cholera Vibrios
Sterile bay water, low tide	160,000,000	4,000,000	3 days	285 days, still living

To ascertain whether the *Bacillus coli communis* would have a similar effect upon the vibrios, 200 c.c. of bay water was sterilized and to it 160 million *Bacillus coli communis*, together with 4 million cholera vibrios, were added. As may be seen by a reference to Table VIII, the *B. coli communis* disappeared within 3 days, whereas the cholera vibrios were still alive at the end of 285 days. A strain of

cers, which we know to be usually of bacterial origin or subsequent involvement, and I was very favorably impressed with the rapidity with which these lesions became clean and healed. This led me to the reasonable deduction that this powerful, non-irritating antiseptic could be used successfully in other eye infections, and I began to employ it in my gonorrheal cases. This proved so satisfactory that I have long since adopted it as my routine treatment for gonorrheal ophthalmia.

The duration of gonorrheal ophthalmia under this method of treatment is 24 to 48 hours after the first application. In most cases but one application was found necessary; in none were more than two such treatments given. Gonococci were rarely found after the first application; where they did so appear a second application effectively disposed of them. After the cessation of the purulent discharge a mild astringent, such as a 1/3 per cent. solution of zinc sulphate, was ordered instilled for a few days.

A 25 per cent. solution of cresatin in albolin was found to possess definite prophylactic value, and is regularly employed in my institutional and private work in gonorrheal ophthalmia.

The technique is simple, but must be followed accurately to obtain the best results. The conjunctival sac must first be cleared entirely of secretion, by means of a stream of warm physiological saline or saturated boric acid solution, preferably through an undine. This is followed by the instillation of a drop or two of a 1 per cent. solution of holocaine or cocaine to prevent the slight irritation of the next step. Allowing a few moments for the anesthetic action to occur, a small cotton swab, mounted on a tooth-pick, is used to apply a drop of cresatin to the mucosa of the conjunctival sac. It is imperative to cover the entire surface of the mucous membrane in this application. No force is used, and particular care is exercised to avoid injuring the cornea. The after-treatment consists in keeping the conjunctival sac free should more pus form, and the repetition of the application, should occasion demand.

The following case records are typical:

CASE I.—A. B., aged one week, seen in consultation with Dr. M. Zigler. Typical ophthalmia neonatorum, gonococci found. Conjunctiva thoroughly flushed, cocaineized, and swabbed with pure cresatin. Marked improvement followed at once and cure was effected without complications. No further application was needed.

CASE II.—Gertrude B., aged two weeks, referred by Dr. N. B. Martin. Gonorrheal conjunctivitis dating from child's second day. Treated in a maternity hospital until seen by me. Intense conjunctivitis, profuse discharge, chemosis, small ulcer of the right cornea. Gonococci present. The eyes were thoroughly flushed, cocaine instilled, and the mucous membranes painted with the drug, full strength. The corneal ulcer was also lightly touched with the swab. Warm boric irrigations and compresses were ordered. After twenty-four hours, mother returned and reported that the eyes had been free from discharge save for slight pasting of the lids after a night's sleep. A second application was made, after which the discharge did not recur. The ulcer of the cornea was found healed on the third day. No recurrence nor complications.

CASE III.—Margaret F., nurse in charge of vaginitis ward of an institution. Most intense gonorrheal conjunctivitis; had to be escorted to my office, being blinded by rapid accumulation of pus and edema. Marked chemosis, conjunctival hemorrhages, and edema of the lids. Gonococci demonstrated. Routine application, as described, was made, and patient requested to wait until arrangements for her transfer to a hospital could be made. After some thirty minutes, and before the transfer could be effected, the patient

announced that her eyes felt vastly improved, and requested permission to wait until the following morning at home. This was granted, and the following morning the patient reported that discharge had stopped a few hours after the treatment. The edema of lids and conjunctiva had disappeared over night. No gonococci could be found, but in view of the intensity of the infection, a second precautionary treatment was given. The following day the patient was given permission to return to her ward duty.

CASE IV.—M. B. K., age 10 days; seen in consultation with Dr. M. Kutscher. Purulent discharge and edema of left eye dating from third day, followed by same condition in right eye three days later. Typical ophthalmia neonatorum; gonococci present. Treated as above described. The next day the eyes were clear; no edema or discharge. No further application needed.

CASE V.—L. J., age 13 days, treated under my direction, shows advantage of adhering strictly to the technique described. Conjunctiva involved since third day of life; profuse discharge, intense edema, free conjunctival hemorrhage; gonococci present. The attendant modified my instructions, instilling a drop or two of 25 per cent. cresatin in albolin into the eyes instead of swabbing with full strength. After twelve hours discharge much diminished, edema less. Conjunctiva then swabbed again with the 25 per cent. solution. Next day both eyes were open, discharge absent in one eye, much diminished in other. A third treatment sufficed to clear the eyes entirely.

206 WEST NINETY-SECOND STREET.

TWO UNUSUAL STRAINS OF DIPHTHEROID BACILLI.

A PRELIMINARY NOTE.

By RALPH R. MELLON, M.Sc., M.D.,

ANN ARBOR, MICH.

It is merely my intention at this time to put on record in brief fashion some of the characteristics of two rather novel strains of diphtheroid bacilli. In a future article their characteristics, both cultural and biological, and their relation to other members of the same group, will be discussed more in detail.

The first strain was recovered from the lung of a patient on whom a diagnostic puncture was performed. The first generation grew very slowly on blood agar. About ten days later the patient died suddenly. Sections of the lung showed definite and interesting pathological changes; it contained many colonies of the bacillus whose relation to the condition is problematical at present.

Culturally, the organism shows a most remarkable pleomorphism. Under proper environmental conditions, it will grow in chains of cocci that are morphologically indistinguishable from the streptococcus. However, this form can be made to take on again the bacillary shape. It shows pronounced activity toward the different sugars, particularly glucose, lactose, dextrin, glycerin, saccharose, salicin, maltose, and inulin, all of which it ferments with acid but no gas production. Such a wide range of sugar fermentation has not been described in diphtheria-like organisms.

The feature of paramount interest lies in its pathogenicity for rabbits. They lose weight rather rapidly after injections of relatively small doses, and eventually die of septicemia. The most noteworthy lesions produced so far are acute suppurative arthritis, cholecystitis, and focal myositis. Subcutaneous hemorrhages have been inconstantly produced. So far, the bacillary form has not been recovered from the lesions, although the coccoid form has been found without difficulty, and has precisely the same qualitative sugar reactions as the strain injected. These localizations are identical

with those produced by certain strains of streptococci, but on this account I do not wish to be interpreted as having accomplished any transmutation in the biological sense. I am inclined to regard this phenomenon as one of extreme pleomorphism only. This diphtheroid gives promise of being a member of a group much more closely related to the streptococcus group biologically than has been known before. Usually we do not think of any similarity between them. Its proper relation, however, can be established definitely only by a study of its immunological reactions, which study is under way at the present time.

The other diphtheroid was isolated from a blood culture of a patient who showed very severe obstructive circulatory disturbances with a low type of fever, all of which followed negligent treatment of a severe wound in the foot, caused by a rusty nail. In addition, the patient showed marked albuminuria.

This organism has so far been a strict anaerobe, with fastidious cultural requirements in other respects. It is strongly gram positive, and strains readily with the simple dyes. It has, after several generations, become chromogenic and has shown ordinary pleomorphism. It is pathogenic to rabbits, injections of relatively small doses producing a high grade of albuminuria and rather rapid loss of weight. This animal's serum shows agglutinins and lysins in low dilutions.

Since the vast majority of diphtheroid strains are at present thought to be non-pathogenic, and in light of the speculation caused by Bunting's notion of their relation to Hodgkin's disease, the isolation of any pathogenic members of the group is of especial interest. A more comprehensive report will appear in the near future.

Medicolegal Notes.

Accident Insurance—Cause of Death, Accident or Disease.—In an action on an accident policy the plaintiff claimed that the insured's death was caused by a strain while attempting to lift a heavy stove. Two days afterward he was treated for pleurisy and three months afterward he died, the first physician who treated him testifying that death was due to Bright's disease, and a physician who was subsequently called in testifying that he found valvular heart trouble. It was held that death was due to causes other than an accident. If a diseased condition was caused by an accident, or existed prior to the accident and had no causal connection with the injury or death resulting from the accident, the accident is to be considered as the sole cause; but if the disease in question existed at the time of the accident and cooperated with the accident to cause a severe injury leading to death, then the accident cannot be regarded as the sole cause of death.—*Robinson vs. United States Health & Accident Ins. Co.*, 192 Ill. App. 475.

Unlawfully Practising Medicine—"Masseur."—In proceedings under the Texas medical practice act for unlawfully practising medicine, R. E. Tyler testified that he went to the defendant's office and complained that he had appendicitis, and told the defendant that he had had a violent attack some five weeks before his call. The defendant told him he did not look like a man who had appendicitis, but that he was suffering from inflammation of the colon, and proceeded to treat Tyler for that affliction, saying he could cure him in a little while. He first gave Tyler an enema, saying it was necessary to wash out his stomach. He then had him lie down and rolled two pillows, placing one under his hips and the other under his chest, there being nothing under the center of the body. He then moved him up and down, pushing him clear to the table. After giving this treatment for a while, he placed Tyler on another table, and gave him an electric treatment. Without going further

into the treatment, he told Tyler when the latter was leaving the office that he must eat nothing but soup and milk, and must leave off all heavy food, especially meat.

As a matter of fact, Tyler was not sick with any disease or disorder when he went to see the defendant, but went there at the instance of others to see whether or not he was practising medicine within the provisions of the act and making a charge therefor. He paid the defendant \$3 for the treatment. A witness who went with him corroborated him. The defendant contended this made them accomplices. The court held that these men, knowing or believing that the defendant was practising medicine in violation of law, went there to detect him, and under no rule of law would their acts constitute them accomplices. Their testimony was clearly admissible.

Another witness testified that the defendant treated him for an affection of the hand and arm; that his hand just hurt, elbow ached, and muscles of the arm hurt. The defendant treated him for some time, and charged him \$25. He gave the witness an electric treatment with a battery, and also gave him what is termed a "hot air" treatment, putting his hand in a "sweat box." He told him he could cure him, but he did not do so, although he underwent treatment for some two or three months. The defendant's contention was that he was a "masseur," and therefore did not have to obtain and register a certificate. As this was his contention, it was held permissible for the State to show that he was treating disease by other means and methods than that usually ascribed to a masseur, and the trial court did not err in admitting this testimony, nor in admitting evidence that he had an account at a drug store for medicines, and in one instance had prescribed and had furnished a salve for application to a sore on the leg of a patient.

The testimony of three witnesses for the defendant was held properly excluded. He did not state that he expected to or could have proven by these witnesses that the treatment given by him to Tyler, and which he admitted giving, was the treatment of a "masseur" in his particular sphere of labor. It was true he offered to prove by them that a "masseur" treatment was good for a certain character of ailments, but the fact that he advertised and held himself out as a "masseur" would not prevent the State from showing, if it could, that he treated his patients by other means than those customarily used by a "masseur" in his particular sphere of labor. The giving of an enema, treatment by electrical machinery, and by the use of a hot-air apparatus, do not come within the means and modes usually ascribed to the sphere of a "masseur" in the treatment of a disease, and as used by them aforesaid, and could not come within the exemption as defined by the Legislature in exempting a "masseur" in his sphere of labor.

The act provides that any person is "practising medicine" when he publicly professes to be a physician or surgeon, or offers to treat any disease, deformity, or injury by any system or method, or to effect cures thereof. The court held that one professing to be a "masseur" is a "physician" when he professes to cure diseases or disorders. And this need not be solely by administering medicines. The conviction was affirmed. *Hyroop v. State*, Texas Court of Criminal Appeals, 179 S. W. 876.

Revocation of License—State Board's Decision on Merits Not Reviewable by Certiorari.—Under the Colorado statute, Rev. St. 1908, sec. 6068, the Supreme Court of Colorado holds that the State board of medical examiners is invested with power to revoke a physician's license for procuring or aiding in procuring a criminal abortion, and where a sworn complaint is filed, charging such offense, and the accused appears and contests the proceedings on their merits, the board has jurisdiction of the subject-matter and the person. Since a tribunal has jurisdiction of a controversy whenever the law requires it to pass upon the questions of law and fact involved, a duty rests upon the State board of medical examiners under the statute, after hearing evidence as to the guilt or innocence of the accused, to decide whether the evidence is sufficient to convict. Where an inferior tribunal has jurisdiction to convict, as shown by the record, the inquiry upon certiorari cannot be extended to a review upon the merits, since upon every question but that of jurisdiction the action of the inferior tribunal is final.—*Thompson v. State Board of Medical Examiners*, Colorado Supreme Court, 151 Pac. 436.

ANTIVENINE IN SNAKEBITES.

A RARE accident, rare at least in cities, occurred here last week. A keeper of the reptile house in the Zoological Park, on January 27, about 8 A. M., was bitten by a rattlesnake (*Crotalus atrox* of Texas) on his right hand, one fang penetrating deeply between the second and third metacarpal bones. The wound was sucked immediately and a double ligature applied. An hour later the physician of the park injected 10 c.c. of Calmette's antivenine, repeating the dose in another hour. In spite of these injections the hand and arm swelled to an enormous size, the pain was extreme, and vomiting set in. The patient was transferred to the German Hospital, and the next morning, as the symptoms had not improved, another injection of 20 c.c. of Calmette's serum was given. Fortunately Dr. Vital Brazil, the founder and director of the Sero-therapeutic Institute of S. Paulo, Brazil, who had been attending the Pan American Congress in Washington, was found in his hotel and at once offered to inject about 20 c.c. of the anticrotalic serum which is manufactured at his Brazilian institute. This was done at 5 P. M. when the symptoms, with the exception of the swelling, subsided very quickly. The following day the hand was still much swollen and discharging a bloody serum from the incisions, but the swelling of the arm was less. On January 30 the arm was still somewhat swollen and discolored as though from a severe bruise, but the patient was feeling comfortable and exhibiting all the signs of quick recovery.

Venomous snakes are divided into two great families—the *Colabridæ venenosæ*, or Cobras, and the *Viperidæ*. With the exception of the beautiful coral snake, a sluggish and almost non-aggressive cobra, all the poisonous snakes of the United States belong to a subfamily of the vipers, the pit vipers, so called from a pit between the eye and the nostril. Most of them are rattlers, i.e. bearing a series of horny rings at their tail end; a few, like the moccasin and the copperhead, have a pointed horny tip at the end of the tail. They are scattered all through the United States and, although receding before advancing agriculture, are in unpleasant evidence in many localities. Compared with tropical countries, our mortality from snakebite is trifling (e.g. in Brazil the annual average of snakebites is estimated at 20,000, with a mortality of 25 per cent.), but the keeping of correct statistics would disclose

quite a number. But, although the mortality is low, the other consequences are serious enough to attract the attention of the medical profession. Tedious suppurations, neuroses, and long continued emaciation are not rare.

Just as the poisonous snakes are divided into two main families, so their venom is of two types, the one abounding in neurotoxin (peptone of Weir Mitchell and Reichert), the other in hemotoxin (globuline of Weir Mitchell). These two toxins are undoubtedly the most important ingredients of all snake venoms. The more powerful of the two is the neurotoxin, which has a selective affinity for certain nerve cells of the medulla, those in the centers of respiration and deglutition. The other prominent ingredient, the hemotoxin, attacks the blood and the blood vessels; its various constituents are agglutinine, hemolysine, and particularly hemorrhagine, also a substance which destroys the bactericidal power of the plasma.* The combination of all these different toxins explains the well known symptoms of snakebite. But when we consider further that the venom of every snake differs from that of every other, each venom representing a mixture of varying percentages of toxins, and that the neural toxin of a cobra differs from that of a rattlesnake, the hemotoxin of a rattlesnake from that of a moccasin, etc., we shall not be surprised to find every snakebite followed by a series of varying symptoms.

The therapy of snakebite in former centuries, which offers an endless list of infallible remedies, proves the utter helplessness with which these accidents were confronted. It was only when the interaction of toxin and antitoxin began to be worked out, when, for instance, Behring gave to the world his diphtheria antitoxin, that Calmette of Lille, France, and almost simultaneously Fraser of Edinburgh, offered an entirely new mode of treatment with their respective antivenines. Calmette, formerly an army surgeon in Cochin China, worked almost exclusively with cobra venom, believing that this would suffice for all types of snake intoxication. Even when, later on, the reports from cases of viper poisoning were not so favorable, he insisted that his antivenine should be of great value in all cases, since it neutralized the paramount toxin of any venom, the neurotoxin, and thus gave the body a chance to overcome by its own resistance the less active toxins. While no doubt this is true to a certain extent, later observations have tended to confirm Behring's law "that every toxin requires its specific antitoxin." In the case reported above, grave symptoms persisted even after four injections of Calmette's antivenine, while the injection of Brazil's anticrotalic serum subdued them immediately.

The widespread existence of poisonous snakes is a constant menace to our rural population, and we are therefore faced with the problem of how to secure a supply of these invaluable antivenines. The tedious process of manufacture coupled with the

*Those who are interested in this subject are referred to the elaborate volume of Hideyo Noguchi on "Snake Venoms," and to the article by Langmann on "Poisonous Reptiles" in the forthcoming Vol. VII of the "Reference Handbook of the Medical Sciences."

comparatively small demand precludes private enterprise. It would therefore seem to be a matter for government supervision. The activities of the United States Public Health Service are many and various, but it would probably be feasible for the Hygiene Laboratory to add this to its already long list of investigations without impairing its usefulness in other directions. It should be borne in mind also that many of these questions of toxins and antitoxins are of highly scientific interest; that snake venoms are of great stability and equability, qualities the absence of which renders the working with other toxins so uncertain and so unsatisfactory. It is a field which offers much to interest the laboratory worker, especially the immunologist.

PREPAREDNESS.

THAT the resisting power of the body politic in this land will have to be increased if it is to be in condition to overcome the incursion of some foreign enemy before or soon after the present European epidemic wears itself out is a self-evident fact. That it is better to have this power of resistance constantly at its point of greatest efficiency, so that the threatened infection can be prevented from establishing itself, rather than to have to resort to the vaccine of conscription after the damage is partly done is also a self-evident fact, though it may be and is denied by certain prophylactic nihilists. If the present Congress does not increase the Army and Navy, the next most assuredly will do so. Most of the details of this increase do not concern medical men as such, but only in their character of citizens; they are, however, vitally concerned that the size and efficiency of the Medical Corps, in both services, shall be increased *pari passu* with the increase in fighting men and equipment. At the present time the number of officers in the medical services of the Army and Navy is far below what is required for a peace footing, below even what it was proportionately in 1861 at the beginning of the Civil War. The total number of available army surgeons, including those in the Medical Reserve Corps and the National Guard, is only a little over 2,000, comparatively few of whom have had adequate training or experience, whereas there should be at least ten times that number of men perfectly fit and adequate to meet any medicomilitary emergency.

Congress is notoriously indifferent, if not hostile, to the medical needs of the public service and will seldom listen to any calls for improvement in the medical corps of the Army or Navy, in the way either of an increase in numbers or of a betterment in rank and pay which would serve to attract good men. On the contrary, it seems, as in the Hay bill, now before it, which would abolish the Medical Reserve Corps of the Army, to be especially inimical to this branch of the service. It would no doubt sanction the erection of architecturally beautiful and medically useless military hospitals in every cross-roads village, but would economically refuse an appropriation to obtain the medical officers to run them. What we have to hope from a Congress whose members are not stimulated to

action by repeated pricks from their constituents may be learned from what happened in 1901. At that time the Dodge Commission, appointed by the President to ascertain the cause for the sanitary débacle of the Spanish war, made its report in which it was urged among other things that Congress make provision for a larger force of commissioned medical officers, the necessity for such increase being amply proved. Congress thereupon passed an act for the reorganization of the army in which, in spite of this report and the recommendation of the Surgeon General, the proportion of medical officers was actually decreased, promotion was made more difficult, and the service in general was made less attractive. It was not until 1908 that the present good but still inadequate organization was effected.

It is therefore most probable, indeed practically certain, that Congress will ignore the Medical Corps, while providing for an increase in the Army, unless it is forced by the physicians of the country to take the necessary action. A beginning in the right direction was made by the Southern Medical Association at its meeting in Dallas last November. At this meeting the Secretary of War was petitioned to make adequate provision in the bill for the reorganization of the Army, about to be presented to Congress, for a sufficient number of medical officers, aggregating a proportion of at least 0.75 per cent. of the enlisted strength of the Army, and also to make provision in this reorganization for the expansion of the Medical Department at the beginning of war by calling into service all members of the Medical Reserve Corps. The Medical Society of the County of New York, at its meeting on Monday of last week, also gave forcible expression to the need of medical preparedness so as to avoid a repetition of the sad and disgraceful experiences in the war of 1898. These examples should be followed by every medical society in the country, and resolutions should be adopted and sent, with personal letters from individual members, to their representatives in Congress demanding an adequate and proportional increase in the Medical Corps, the expansion being largely in the higher grades so that the chances of promotion may be greater and the service be made more attractive to men of education and ability.

In addition to this, there should be greater activity in preparing those medical men in civil life, who may be called to serve in time of war, to perform the duties to which they may be assigned. A correspondence school for instruction of members of the Reserve Corps has been, or is about to be, established, and the knowledge so gained should be supplemented by practical instruction in summer camps and elsewhere during stated periods once or twice a year. In the general awakening to the dangers that threaten the peace of our country and to the parlous state of our defences, the medical profession must be ready to respond to any call and to meet any military emergency that may be presented to it. As we have before suggested, the physicians in civil life should take thought as to how they can do their part in case of war. There should be some plan of action determined upon before the emergency

arises. If the emergency does not arise no harm will have been done; if it does, much uncertainty and needless confusion will be avoided if each one has determined in his mind what course he will take. Those who can take an active part should announce their willingness to do so; those who by reason of family obligation, ill health, or age must stay at home can arrange to care for the patients of their colleagues who are called to the service.

REFLEX RESPONSE TO EMOTIONAL STIMULATION.

CERTAIN strong emotions within us call forth a quick, instinctive response. The outward manifestations of this response reveal its primitive nature and its similarity to that found in animal life. The researches of the physiological laboratory, therefore, may well serve to throw light upon its nature and its usefulness in the economy of life. How do the emotions influence the nervous system in its function of adjustment and adaptability to the conditions which call forth the emotion?

Walter B. Cannon (*Bodily Changes in Pain, Hunger, Fear and Rage*, D. Appleton & Company, 1915) has published the results of some experimental work, in which he has thrown some light on this problem. He has made some valuable contributions to the knowledge of the interaction of the sympathetic division of the vegetative nervous system and the secretion of the adrenal glands. He proves through varied experiments the sympathetic innervation of these glands, and their stimulation to secretion when the sympathetic nerves are under emotional influence. Further, he shows that the adrenin thus secreted exerts a direct influence upon the bodily organs concerned in the response to the emotions, while at the same time it cooperates with the action of the sympathetic system itself. The effects produced are a distribution of blood to those parts which are to be specially called into activity, increased blood pressure, hastening of coagulation, removal of muscular fatigue, increased respiratory power. There is also an increase of sugar supply in the blood, which prepares for unusual exertion. It is thus evident that the emotions so far control the nervous mechanism as to prepare for those reactions which are demanded by the situations in which the emotions arise. These reactions, though involuntary, are purposive, and it is on the ground of their utility that they have become established through the principle of "phylogenetic association."

This study gives us one phase of the intricate interaction and interdependence of the psychic activity and that of the vegetative level of the nervous system. It is suggestive of more extensive fields yet to be explored, in which we shall come to know more of this still obscure but fundamentally important subject. The study has dealt with certain more obvious emotions, but it will doubtless pave the way to a similar understanding of the deeper fundamental emotions from which these arise, as well as of their intricately finer and more complex developments. In short, it may be one step on the way to understanding the interaction of the vegetative nervous system and the unconscious no less than the conscious psychic life.

CHILD-LABOR PROBLEM IN RELATION TO HEALTH.

THE question of child labor has always been a vexed one. It is well known—indeed it could not be otherwise—that young children should not be employed in manual labor or forced to work for long hours under whatever conditions. In Great Britain child labor has been forbidden for a considerable time and naturally the results have been most satisfactory. In the report of the Surgeon General of the Public Health Service for the fiscal year ending June, 1915, child labor in Massachusetts is discussed. In January, 1915, the Massachusetts State Board of Labor and Industries requested that Assistant Surgeon M. V. Safford should be authorized to assist the board in the problems which confronted it with respect to the employment of child labor in the State, and he was accordingly detailed with the board under instructions contemplating a study of the effect of various occupations on persons during their period of adolescence. In May last under the direction of Dr. Safford comprehensive physical examinations were made of minors employed in the textile industries of the State, the examinations being in accordance with a prescribed scheme calculated to bring out and record any abnormal conditions possibly attributable to the individual's particular occupation or working conditions.

While sufficient data have not yet been accumulated to warrant positive deductions as to the effect or non-effect of the various kinds of work in the textile industries upon minors employed therein, enough has been done to make a prediction as to conclusions fairly safe in certain matters of practical interest. For example, an undue proportion of boys employed have been found to be under height and weight for the ages given, but such deficiencies have been found to bear no relation to the duration of employment in the textile industry. To some extent such deficiencies are more apparent than real and are to be accounted for by successful evasion of the State laws with respect to the age and home employment of minors. However, no conclusion can be come to until the investigations have been completed; but as far as these have been carried it would seem safe to assume that the deficiencies of intelligence and physical strength already discovered among child workers are owing in a greater or lesser degree to their employment, which, in effect, means that children should not be allowed to work.

EPIDEMIC SEPTIC SORE THROAT.

ANY physician who has had occasion to treat a case of septic sore throat will admit the seriousness of the condition and recognize the gravity of the complications which may develop. Unfortunately the treatment is of little effect and therefore the greatest stress must be laid on the prophylaxis. Krumwiede and Valentine were able to study an epidemic of two hundred and thirty-two cases and traced the source of the infection to the milk supply (*Jour. Med. Research*, 1915, XXXIII, 231). On further search they found that the beginning of the trouble was the appearance of a sore throat in one of the persons at the dairy and that from this person it spread to a milker and from him to

the cow. Streptococci isolated from one cow showed cultural characteristics identical with those isolated from patients although the cow gave no evidence of mastitis. On the other hand one cow in the herd which obviously had a mastitis, showed a streptococcus which was different and which probably had no relation to the epidemic. They show that the use of poured blood agar plates is quite essential for the recognition of hemolytic streptococci which are characteristic of the disease. This is strong confirmatory evidence, were it needed, that such milk-borne epidemics are primarily of human origin and that careful supervision of the personnel of the dairy is all-important. At the same time it emphasizes one of the dangers against which the inhabitants of this city are protected by the Health Department's regulation demanding the pasteurization of the milk supply.

THE AVITAMINOSES.

It was inevitable that this term should be coined to express the old-new group of deficiency diseases due to defective alimentation. We naturally imagine that an avitaminosis must be general and never purely local, but it is by no means impossible that some sensitive organ may alone show functional impairment. The acquired nyctalopia of trench fighters may be a case in point. While this symptom has been regarded in some quarters as purely psychogenic, other ophthalmologists are accusing the unbalanced diet of the troops. In the *Muenchener medizinische Wochenschrift* for December 14, Wietfeldt records the fact that this night-blindness is much more marked in winter than in summer. With the beginning of May fresh vegetables come into use, and it is believed at present that the vitamins are contained in fresh fruits, fresh vegetables, and meat. Overcooking, however, can destroy the vitamins in these food articles. The author therefore recommends the use of fresh fruit juices to make good the defects of the commissary and field kitchen, especially in the winter months. The apple crop has been abundant and apple juice is available during the entire cold season. Citric acid lemonade, however, is an artificial product which contains no vitamins.

News of the Week.

Health Insurance.—There has recently been introduced into the State Legislature of New York a bill providing for compulsory health insurance for workers in the State, which aims to supplement the present State Workingmen's Compensation Law by giving medical attention and cash benefit to workers disabled by sickness as well as by accident. The plan differs in principle from the existing industrial accident compensation in that 40 per cent. of the cost of the health insurance is to be borne by the workmen themselves, 20 per cent. by the State, and 40 per cent. by the employers. The bill has been drafted in cooperation with the American Association for Labor Legislation and the American Medical Association and will cover any case of sickness or accident not within the scope of the present legislation. It will apply to manual laborers and to all others earning less than \$100 a month.

New York City Death Rate.—During the week ending January 22 the deaths reported in New

York City numbered 1,760, an increase of 302 as compared with the corresponding week of last year. The respective rates for the week were 15.99 in 1916 and 13.62 in 1915. Influenza, bronchitis, and pneumonia caused 501 deaths, which was 58 less than during the previous week, indicating that the epidemic of grip and pneumonia was definitely on the wane. The mortality from tuberculosis was lower than during the corresponding week of 1915, while that from heart disease and nephritis was increased by 41 deaths, and that from the acute infectious diseases by 7. During the first four weeks of this year the death rate for the city was 16.47, while for the corresponding period of 1915 the rate was 14.89.

Fire at Sanatorium.—The administration building of the Sanatorium Gabriels at Gabriels in the Adirondacks, N. Y., was destroyed by fire on January 18. The sanatorium is conducted by the Sisters of Mercy for sufferers from tuberculosis, and is entirely non-sectarian. Plans for a modern fire-proof building to replace the one destroyed have already been prepared, and its construction will be begun as soon as sufficient funds, for which an appeal has been issued, are in hand.

Chemical Exports.—The exports of chemicals from the United States during the last year show a tremendous increase as compared with those during 1913, the last year of normal times. It is now estimated that the total value of the chemicals exported in 1915 will exceed \$75,000, as against \$25,000 in 1913. The chief articles in which the increases have occurred are acids, bark extracts, dyes and dyestuffs, and soda salts.

Change at Nurses' School.—The title of the Training School for Nurses at the City Hospital, Blackwell's Island, has been changed by Commissioner Kingsbury to the City Hospital School for Nursing. The commissioner has also abolished the three advisory boards of the school and has formed a single board made up of representatives of the three.

Mount Sinai Hospital to Extend.—A plan for the expansion of Mount Sinai Hospital, New York, into a complete general hospital was announced at a meeting of the Hospital Board of Directors on January 23. Of the \$2,150,000 estimated as necessary for the proper development of the hospital, \$1,400,000 has already been subscribed or contributed. The original plan of expansion, proposed three years ago, called for building expenditures amounting to \$1,100,000, but since that time it has been found advisable to extend the operations. Buildings are now being constructed for the pathological laboratory, the servants' dormitory, a children's dispensary, and a new private pavilion, to be known as the Guggenheim Memorial, while plans for a new children's hospital and the change of the present children's pavilion into a semi-private ward building are being considered. The directors are also considering the establishment of a department of hygiene in connection with the out-patient clinic.

Philadelphia General Hospital.—Dr. S. D. W. Ludlum, Dr. S. D. Ingham, Dr. S. E. Gilpin, and Dr. A. C. Buckley have been appointed members of the Psychopathic Staff and Dr. Charles W. Schaeffer Laryngologist to the Tuberculosis Department.

Hospital Dedicated.—The new buildings of the New York Orthopedic Dispensary and Hospital at 420 East Fifty-ninth Street, New York, were formally dedicated and opened on January 31.

Personals.—Dr. FRANCIS D. PATTERSON of Philadelphia has been appointed chief of the Division

of Industrial Hygiene and Engineering of the Bureau of Inspection in the Department of Labor and Industry of Pennsylvania, succeeding the late Dr. John C. Price.

Dr. LELAND E. COFER, assistant surgeon-general of the United States Public Health Service, has been nominated by Governor Whitman as health officer of the Port of New York. Dr. Cofer was assigned to the State's service by President Wilson after the recent death of Health Officer O'Connell to remain in charge pending the transfer of the quarantine supervision to the Federal Government from the State. A bill providing for the transfer and for the abolition of the position of health officer has been introduced into the Legislature, and Governor Whitman has sent a special message urging its passage.

Stony Wold Sanatorium.—At the fifteenth annual meeting of the Stony Wold Sanatorium, Lake Kushaqua, N. Y., which was held in New York on January 26, it was reported that during the year 114 patients had been accommodated, 369 applications had been received, and 221 patients treated. The expenditures of the year totaled \$99,224. Mrs. James E. Newcomb was reelected president of the corporation.

Gifts to Charities.—A number of charitable institutions receive bequests under the will of the late Archibald M. Stewart of New York, among them the Presbyterian Hospital to which \$5,000 is given.

By the will of the late Dr. Isaac Ott of Easton, Pa., his estate, bequeathed to his widow for life, reverts on her death to the University of Pennsylvania, for the establishment of the Isaac Ott chair of Physiology. Also by his death provision is made for the establishment of a memorial chair of physiology in the Medicochirurgical College through the will of his mother.

By the will of the late James Hay of Philadelphia bequests are made as follows: \$25,000 to the hospital of the Protestant Episcopal Church at Philadelphia for the endowment fund, \$5,000 to the Philadelphia Home for Incurables.

Two contributions amounting to \$49,000 were recently received from anonymous donors by the Brooklyn Hospital for the \$250,000 fund required to complete the new buildings. One contribution of \$28,000 is to be used to finish, equip, and furnish the nurses' home; while the other of \$21,000 will be used for the private ward pavilion. A large number of smaller contributions have also been received for the fund.

The Northern Dispensary, New York, receives a bequest of \$5,000 under the will of the late Lambert Snydam of this city.

St. Luke's Hospital, New Bedford, Mass., and the Presbyterian Hospital and St. Rose's Free Home for Incurable Cancer, New York, receive \$5,000 each by the will of the late Mrs. Clara E. Seabury of New York.

Bequests of \$5,000 each are made to the Methodist Episcopal Hospital and the Norwegian Deaconesses' Home and Hospital, Brooklyn, N. Y., by the will of the late William Todd of that city.

By the death of his daughter, recently, the following bequests in the will of the late Jacob G. Neafie of Philadelphia have become operative: The Hahnemann Hospital, Philadelphia, \$35,000; the Philadelphia Home for Incurables, \$15,000; the Hospital of the Protestant Episcopal Church in Philadelphia, \$10,000.

The Hospital of the Protestant Episcopal Church

and the German Hospital of Philadelphia received bequests of \$1,000 each under the will of the late Daniel W. Graftly of that city.

Lawsuit over "Autolysin."—A suit was entered in the Supreme Court of New York last week by Dr. Silas P. Beebe and Dr. A. Judson Quimby against Dr. J. Wallace Beveridge, who has been associated with them in the manufacture and sale of "autolysin" as a cure for cancer. Dr. Beebe and Dr. Quimby ask that the partnership which they had formed with Dr. Beveridge be dissolved and that a receiver be appointed to take charge of the concern.

The American Association of Medical Jurisprudence will meet in Washington, D. C., on Saturday, May 6. Dr. William A. Woodward has been appointed chairman of the committee of arrangements. The president of the association is Dr. D. Percy Hickling of Washington; the secretary, Mr. Charles P. Blaney, 26 Liberty Street, New York.

Harvey Society.—The sixth lecture of the series will be held at the New York Academy of Medicine, 17 West Forty-third Street, on Saturday evening, February 5, 1916, at 8.30 P. M., by Dr. Hideyo Noguchi of the Rockefeller Institute for Medical Research. Subject: "Spirochetes."

Western Reserve Medical Department.—The following new appointments in this school have been announced: Dr. J. Rogoff, formerly of the department of physiology and pharmacology, Vanderbilt Medical School, Nashville, to be instructor in experimental medicine; Dr. C. H. Fiske, formerly assistant in biological chemistry, Harvard Medical School, to be associate in biochemistry; Dr. R. W. Scott, formerly demonstrator of medicine, Western Reserve University, to be instructor in physiology.

University of Oregon.—The fund for the new buildings of the University of Oregon Medical Department, Portland, has been increased by a contribution from four of the business men of the city of \$25,000, thus making available the \$50,000 appropriated by the State. It is now proposed to raise an additional \$100,000.

Medical Society Elections.—CENTRE DISTRICT-MERRIMACK COUNTY (N. H.) MEDICAL SOCIETY: Annual meeting at Concord on January 11. Officers elected: *President*, Dr. Burt W. Carr, Pittsfield; *Vice-President*, Dr. Loren A. Sanders, Concord; *Secretary-Treasurer*, Dr. Charles Duncan, Concord; *Censor*, Dr. N. L. Griffin, New London.

HARTFORD (CONN.) MEDICAL SOCIETY.—At the annual meeting held on January 3, officers for the ensuing year were elected as follows: *President*, Dr. Joseph E. Root; *Vice-President*, Dr. C. C. Beach; *Secretary*, Dr. Amos T. Harrington; *Assistant Secretary*, Dr. Howard W. Brayton; *Treasurer*, Dr. Philip D. Bunce.

FRESNO COUNTY (CAL.) MEDICAL SOCIETY.—Officers for 1916 were elected at the annual meeting on January 5, as follows: *President*, Dr. L. R. Willson; *Vice-Presidents*, Dr. H. J. Craycroft and Dr. J. H. Pettis; *Secretary*, Dr. Kenneth J. Staniford; *Assistant Secretary*, Dr. C. D. Sweet; *Treasurer*, Dr. T. M. Hayden.

COPPER COUNTRY (MICH.) MEDICAL SOCIETY.—At the annual meeting held at Houghton on January 3, the following officers were elected: *President*, Dr. P. D. Bourland, Lake Linden; *Vice-President*, Dr. John MacRae, Calumet; *Secretary-Treasurer*, Dr. G. A. Conrad, Houghton.

CINCINNATI (OHIO) ACADEMY OF MEDICINE.—

Officers as follows were elected at the annual meeting of the Academy held on January 3: *President*, Dr. Charles T. Souther; *First Vice-President*, Dr. D. T. Vail; *Second Vice-President*, Dr. J. E. Pirrung; *Secretary*, Dr. W. R. Abbott; *Treasurer*, Dr. A. G. Deury; *Librarian*, Dr. Archibald I. Carson.

SUMNER COUNTY (TENN.) MEDICAL SOCIETY.—The following officers were elected at the annual meeting on January 13: *President*, Dr. T. Y. Carter, Westmoreland; *Secretary-Treasurer*, Dr. J. R. Parker, Gallatin.

PIMA COUNTY (ARIZ.) MEDICAL SOCIETY.—At the annual meeting held at Tucson on January 11, the following officers were elected: *President*, Dr. C. A. Thomas; *Vice-President*, Dr. S. H. Watson; *Secretary*, Dr. T. R. Pratt.

BERRIEN COUNTY (GA.) MEDICAL SOCIETY.—At the annual meeting held at Nashville on January 13, the following officers were elected: *President*, Dr. Henry W. Clements, Ray City; *Vice-President*, Dr. J. G. Devano, Adel; *Secretary*, Dr. D. R. Carter, Nashville.

The Late Dr. Barrows.—At a meeting of the Executive Committee of the Medical Board of Bellevue Hospital, held Wednesday, January 26, the following minute was adopted: "The members of the Medical Board of Bellevue Hospital record with sorrow the death of their late associate, Dr. Charles Clifford Barrows. Dr. Barrows for more than twenty years was connected with the Gynecological Department of the hospital, in which he rendered untiring, skillful, and faithful service to the sick poor of the city. His achievements in surgical operations and his devotion to the best humanitarian interests of his patients won their gratitude and respect, while his geniality and kindness endeared him to all those whose privilege it was to be associated with him. It is resolved that this record be entered upon the minutes of the Medical Board of the hospital and that a copy be sent to the family of Dr. Barrows, and to the *New York Medical Journal* and the *MEDICAL RECORD*."

Obituary Notes.—Dr. EDWARD J. COLLINS of Washington, D. C., a graduate of the Department of Medicine, George Washington University, Washington, in 1892, died at his home in Chevy Chase, Md., on January 16, aged 66 years.

Dr. Z. SWIFT WEBB, formerly of New York, a graduate of the College of Physicians and Surgeons, New York, in 1848, died at his home in Waterbury, Conn., from bronchial pneumonia, on January 18, aged 91 years.

Dr. JAMES TWEDDALE of Washburn, Ill., a graduate of Rush Medical College, Chicago, in 1869, and a member of the American Medical Association and the Illinois State and Woodford County Medical Societies, died at his home on January 8, aged 83 years.

Dr. JACOB R. CRESSINGER died of uremia at Philadelphia, on January 6, at the age of 72 years.

Dr. WALTER LOUIS WOERNER of Lititz, Pa., died of pneumonia at Lancaster, on January 7. He was graduated from the Hahnemann Hospital and Medical College of Pennsylvania in the class of 1912.

Dr. ROBERT T. NEFFNER of Weisburg, Ind., a graduate of the Medical College of Ohio, Cincinnati, in 1902, and a member of the Indiana State Medical Association and the Dearborn County Medical Society, was drowned while trying to ford a swollen stream on horseback, on January 12, aged 35 years.

Dr. ROBERT FRED NITSCHKE of Dubuque, Ia., a graduate of Rush Medical College, Chicago, in 1877,

died at his home, from bronchial pneumonia, after a short illness, on January 9, age 86 years.

Dr. GUY HOLBROOK, formerly of Lowell, Mass., a graduate of the Albany (N. Y.) Medical College in 1866, formerly an alderman and a member of the Board of Health of Lowell, and a member of the Massachusetts Medical Society, and the New Hampshire Medical Society, died at his home in Boston, on January 16, aged 70 years.

Dr. ALFRED IRA NOBLE of Kalamazoo, Mich., a graduate of the Medical School of Maine, Portland, in 1886, medical superintendent of the Kalamazoo State Hospital for the last ten years, and a member of the American Medical Association, the Michigan State Medical Society, the Kalamazoo Academy of Medicine, and the Detroit Society of Neurology and Psychiatry, died in Detroit, after a short illness, on January 19, aged 56 years.

Dr. MEREDITH D. JONES of St. Louis, Mo., a graduate of the Jefferson Medical College, Philadelphia, in 1872, emeritus professor of otology in the American Medical College, St. Louis, and a member of the Missouri State Medical Association and the St. Louis City Medical Society, died at Chambersburg, Penn., of heart disease, on January 12, aged 67 years.

Dr. CHARLES IMPEY of Omaha, Neb., a graduate of the Medical Department of the University of Louisville, Ky., in 1874, and a member of the American Medical Association, the Nebraska State Medical Association, and the Omaha-Douglas County Medical Society, died suddenly from cerebral hemorrhage, on January 10, aged 63 years.

Dr. EUGENE MARK WORTHEN of Plymouth, N. H., a graduate of the Dartmouth Medical School, Hanover, in 1901, and a member of the New Hampshire Medical Society and the Grafton County Medical Society, died at his home, after a long illness, on December 29, aged 43 years.

Dr. ARNOLD EBERG of Simsbury, Conn., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1879, died at his home, on January 16, aged 58 years.

Dr. ARTEMUS WARD of Canaan, Vt., a graduate of the University of Vermont, College of Medicine, Burlington in 1881, died at his home, on January 3, aged 69 years.

Dr. HENRY BLANK of Milwaukee, Wis., a graduate of Rush Medical College, Chicago, in 1885, a member of the American Medical Association, the State Medical Society of Wisconsin, and the Milwaukee-Ozaukee Counties Medical Society, and for twenty years professor of orthopedic surgery at the Wisconsin College of Physicians and Surgeons, died at his home from Bright's disease, on January 12, aged 54 years.

Dr. JOHN W. STRICKLAND of Macclenny, Fla., a graduate of the College of Medicine, University of Georgia, Augusta, in 1899, died at his home, after a short illness, on January 15, aged 51 years.

Dr. CORWIN W. CORNELL of Knoxville, Iowa, a graduate of the Rush Medical College, Chicago, in 1871, and a member of the American Medical Association, the Iowa State Medical Society, and the Marion County Medical Society, died at his home, after a short illness, on January 19, aged 66 years.

Dr. JAMES J. DURRETT of Fairmont, W. Va., a graduate of the School of Medicine, University of Maryland, Baltimore, in 1897, and a member of the West Virginia State Medical Association and the Marion County Medical Society, died suddenly on January 20, aged 44 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE PUBLIC MEDICAL SERVICES; NAVAL, MEDICAL, SANITARY—EXPENDITURE OF HOSPITALS—SIR E. CASSEL'S CONTRIBUTIONS—EPIDEMICS—NOTIFICATION OF BIRTHS—MATERNITY—SHELL-FISH.

LONDON, Jan. 8, 1916.

THE time of year has been the chief subject of conversation during the week. Whenever friends casually met the prospect of the future would be alluded to by someone, though the majority turned rather to the past, which naturally provided a greater variety of topics. Of these the public medical services claim special attention from their close relation to the war which absorbs so much of our thoughts. The Naval Department has been carried on as systematically as usual, the Greenwich Hospital School has been transferred to the metropolitan area, and its staff considers the change an advantage. It brings them into contact with the societies and other centers of scientific work, enabling them in turn to report their own proceedings. In the Army Department Major Harrison gives an account of infected wounds treated by lactic acid. Lieutenants Black, Glenny, and McNee add clinical experiences of gas-poisoning to the extent of nearly 700 cases. Lieutenant Treadgold and Surgeon Reece investigated cerebrospinal meningitis as it prevailed among the troops and the public. The motor ambulance service has been greatly developed, ambulance trains being organized in the most complete manner.

The expenditure at our hospitals continues to cause some anxiety, and suggestions are made from various sources with the hope of diminishing it. Some of them have been tried fairly enough and others carefully watched, but the result has not been striking, and indeed with nearly 9,000 beds in daily occupation the total normal expenditure must be large. Last year those beds afforded relief to 134,025 patients, in addition to which 1,321,104 were attended in the several out-patient departments. The total expenditure for the year, including maintenance, administration, rent, rates and taxes amounted to £181,162, being a slight increase over that of the previous year, though the number of patients treated in the period was somewhat less. Among them were 5,478 engaged in the naval and military services. Besides all these the voluntary hospitals provide for still larger numbers. Many comparisons between the different institutions and the cost of working have been circulated but do not seem to excite much interest outside the administrative and medical staffs. The Red Cross work has been rather heavier by the leaving for active service of a large proportion of the members. The cost of working has been affected by the rise in prices of provisions, which renders comparisons with previous years of little value. There is also great uncertainty from week to week in the number of beds actually occupied, sudden, unexpected calls on the one hand compelling all of them to be in constant use, others being at times vacant in readiness to afford accommodations at short notice.

Sir Ernest Cassel's gift of £50,000 for hospitals and charities, which I reported to you, is being distributed in the same way as his former donation of a like sum, that is partly in direct gifts and partly through the King Edward Hospital Fund. The fol-

lowing are some of the amounts already allocated: £800, London Hospital; £500, Kings College; £1,000, Guy's; £300, St. Mary's; £750, Charing Cross; £600, University College; £500, Middlesex; £1,000, St. Bartholomew's. Special general hospitals have also been benefited and many provincial hospitals, both general and special. Sir Ernest has also entrusted the King Edward's Fund with £28,000, with which to increase grants already made by it during the past year.

The absence of members of the staff of hospitals who have gone to the front has been a feature noticed by a number of medical visitors to London, and the same observation applies to the public medical service. A number of the inspectors of the medical department of the local government board are working under the Army Medical Corps, among them the first assistant, Dr. Buchanan, member of the army's advisory committee, who went to the Dardanelles in July to aid in the prevention of epidemic outbreaks. Other inspectors have been engaged in supervising the supply of food products to the troops from Argentina, Brazil, and the United States. The cooperation of the civil and military authorities has been cordial and efficient from the commencement when the water supply, sewerage, disposal of excreta and such subjects were most urgent, and the local medical assistance was of the greatest value to the military officials. The local board and war office authorities from the outbreak of the war have been both engaged in preventing by every means the spread of infectious diseases, and their efforts have been largely successful, as shown by the slight incidence of those diseases, with one or two exceptions. Thus measles was epidemic at Bedford from October to February, during which period there were 534 cases, 63 proving fatal. Cerebrospinal meningitis attacked the troops stationed in different parts of the country early in the year and was a cause of some anxiety at the war office, but the vigorous measures adopted kept it under control. A memorandum concerning it was circulated among medical officers of health. In it special emphasis was laid on the isolation of patients and the supervision of contacts. So, early diagnosis being difficult, the board offered to undertake examination of cerebrospinal fluid sent to its pathological laboratory. Local authorities were recommended in other cases to arrange with local bacteriologists to examine swabs taken from contacts. The notification of measles and German measles was put in force throughout the country under the regulations relating to them of the Public Health Act, 1915. The extension of the notification of births was also the subject of an act passed to make the system of the adoptive act (1907) universal, *i.e.* notice to be given to the medical officer of health of all births. It also requires local authorities to make arrangements for the protection of mothers, of expectant mothers, and young children. The local government board issued in the summer a circular on maternity and the welfare of infants, indicating the scope of the work which ought to be undertaken. The government agrees to provide half the cost of schemes for maternity and child welfare approved by the board and has issued regulations under which grants for these purposes will be paid. Regulations of shell-fish layings have also been made under the act which has given power to local authorities to deal with this subject and which, it is to be hoped, will do away with a danger to the public health.

4. Notes on a Conference of the Medical and Social Aspects of Syphilis of the Nervous System. The Development of the Gold Sol. "Paretic" Reaction as Compared with the Cerebrospinal Syphilitic Type. H. C. Solomon and E. S. Welles.
5. A Non-Fatal Fracture of the Axis. Frederick W. O'Brien.

1. **The Treatment of Nephritis.**—Cadis Phipps reports a number of cases of nephritis, some treated by the usual methods and some treated with thyroid extract. He states that while the cases are too few in number to be of service in drawing any very definite conclusions they suggest the following statements: 1. Any rigorous system of diet may be so strict or continued so long that it may be distinctly harmful to the individual case. 2. More freedom in the allowance of protein than is recommended in the "text-book" nephritic diet may be of apparently great advantage in the individual case. 3. Thyroid extract has, perhaps, a great value in the treatment of nephritis, one of the commonest and, at the same time, one of our most hopeless diseases. 4. If given carefully, the administration of the drug is safe. 5. Thyroid medication in nephritis should receive more attention than has heretofore been accorded it.

2. **The Injured Employee and the Workmen's Compensation Law; Results of Impartial Examinations.**—Francis D. Donoghue calls attention to the fact that the Workmen's Compensation Act in Massachusetts has brought into existence not only a new method of adjudicating claims, but also has created a new and broader field for expert medical service. A clear statement of what is found, a correct diagnosis, and the visualization of an injured employee as he is, under working conditions, are essentials to the sort of medical report which is necessary in passing upon cases under the act. From impartial examination in numerous cases the writer finds that certain reasons stand out as an explanation of the absence in some cases of proper diagnosis, or of the proper application thereof. Among these are the tendency to overlook details and the relationship of various existent factors which later may be extremely important in passing upon subsequent conditions; a habit of mind acquired from examining cases under the old law tending to inhibit that process of deductive reasoning so essential under the theory of the compensation system, danger of failure to realize that a surgical cure is not necessarily a functional cure; failure to realize the importance of occupational diseases and other forms of incapacity due to working conditions and materials, since in such cases considerable care may be required to determine whether the industry is the primary or the secondary cause of disability, or in no way responsible. One point which the writer forcibly emphasizes is that oftentimes a long period of disability may be prevented if a little direct personal interest is taken in the cases of incapacitated employees by employers and surgeons. As complete a study of each case as time and conditions under which the examination is made will permit should be made.

3. **An Outline for the Management of Cardiac Cases from the Out-Patient Department Standpoint.**—Mark H. Wentworth emphasizes the importance of regulating the life of the cardiac patient and especially the need of proper home conditions. In severe cases in which bed treatment is required the diet is all important. The

diet should be light, just enough to keep up nourishment without ever causing a sense of fullness or allowing gas to form. The lacto-cereal diet is best. This is made up of milk, custards, eggs, junket, crackers, swei-back, and toast. Meat should be given sparingly if at all, because the purin bodies tend to raise the blood pressure and the fibers are relatively slow of digestion. The writer gives a sample menu for five light meals a day.

5. **A Non-Fatal Fracture of the Axis.**—Frederick W. O'Brien reports this case because a fracture of the axis in itself is not often recognized in the living. This instance occurred in a boy seven years of age, in whose condition there was nothing remarkable except his carriage. He was unable to move his head without pain and supported his lower jaw along the ramus with his upturned hand. The Roentgen examination showed a complete fracture of the laminae of the axis. Proper orthopedic support was provided and excellent union with complete recovery of function took place.

8. The Treatment of Obesity. Jacob Gutman.
9. The Metabolism of Tissue Autolysis. Bernard Oettinger.

1. **Common Affections of the Eye.**—S. D. Risley reviews the common affections of the eye, particularly those forms of injury, abnormality, or disease, which may fall first under the care of the family physician, such as ophthalmia neonatorum, foreign bodies on the cornea, lime burns, punctured wounds, glaucoma, and phlyctenular disease. In the matter of school hygiene he emphasizes the following conclusions: 1. Before entering school the possible presence of defective vision should be excluded and any existing error of refraction corrected. 2. The probability of harm resulting from the school life diminishes with every added year of age in all states of refraction, therefore our children are placed in school at too tender an age. 2. The co-operation of the family adviser in securing the examination of the eyes of every child before entering school would go far in securing the conservation of vision in the rising generation. Physicians should also discourage the entrance of children into school before the seventh or eighth year of age.

2. **Chronic Tonsillitis.**—Louis Fischer points out that chronic hypertrophic tonsillitis, with frequent exacerbations of fever, headache, vomiting, and anorexia, may be mistaken for gastric or gastro-enteric derangement. The intoxication is due to the absorption of the toxins from the pathogenic bacteria harbored in the recesses of the tonsils. In such cases the examination of urine shows that there is a large amount of acetone, and traces of albumin and acetic acid. No case presenting gastric symptoms should be permitted to pass with such a diagnosis until one has assured himself that there is no chronic inflammatory tonsillitis at the root of the trouble. The danger is not so much in the gastric disturbance, as in the possible endocarditis or nephritis which the repeated tonsillar infection is likely to cause. The treatment is surgical. The tonsils must be enucleated, and the whole of the diseased tissue removed. This procedure should be followed by general restorative treatment.

7. **Allen Treatment in Diabetes Mellitus.**—Samuel H. Paley relates the history of five cases of diabetes

mellitus treated according to the Allen method. From his experience with these cases he finds that a patient with sugar as high as 7 per cent. may become sugar free within three days when starved and given only whiskey. Beginning with small quantities of carbohydrates in the form of non-starchy vegetables in gradually increasing amounts, and later adding protein and fat, a tolerance can be established for the three food stuffs sufficient to maintain the metabolism of the patient and keep him free from glycosuria. Apparently an acute infection, as lobar pneumonia, or a chronic disease, as nephritis, is no hindrance to this form of treatment. The writer's patients took the treatment with no discomfort, except perhaps some weakness during the starvation period. Alcohol apparently had no deleterious effect.

9. The Metabolism of Tissue Autolysis.—Bernard Oettinger makes observations on certain phases of tissue autolysis, reviews opposing theories with reference to these phenomena, and concludes that a common systemic mechanism pertaining to reduction of the antityptic index and consequent tissue autolysis underlies erythrocytal disintegration normally, peptic erosion or ulcer, and the intense jaundice, hemolysis, and extensive organ necrosis noted in profound toxemias. Methemoglobinemia appears as an invariable sequence of erythrocytal autolysis (hemolysis). The greater degree which makes it a dominant feature in some pathological conditions corresponds to the more intense autolysis of fixed tissue cells under the same circumstances. Certain observations suggest that the rôle of methemoglobin in body chemistry may proceed from the fact that it is an oxidizing substance possessing an elective affinity for the intermediate products of metabolism and hence within range of immunity reactions progressing favorably, a saving agency in respect to other oxidizing tissues. In conditions which comprehend an abnormally accelerated and therefore toxic hemolysis, the associated toxic methemoglobinemia may be viewed as one uncontrolled factor of a defense mechanism broken down.

4. The Diazo and Urochromogen Reactions in Pulmonary Tuberculosis.—A. N. Sinclair, from observations on 146 tuberculous patients, draws the following conclusions: 1. The only favorable change from normal (both tests absent) is to a negative diazo and positive urochromogen. (This would also mean that at an original examination it is the only favorable deviation from

normal.) 2. A change from either negative diazo to either positive diazo is most unfavorable. 3. The appearance of both reactions is of most grave portent. Such patients generally die. 4. When there is a change from a positive diazo and a negative urochromogen, the only favorable one is a reversal (that is, to a negative diazo and positive urochromogen). When the change is to positive to both tests a fatal issue is prognosticated. On the other hand, a change to normal (contrary to what we would expect) is of very grave prognosis. If the urochromogen reaction does not appear concomitantly with the disappearance of the diazo (or at least in a day or two) the prognosis is of the worst. 5. The disappearance of the diazo reaction (when both tests have been positive) has not been observed as heralding a fatal issue. 6. The disappearance of the diazo may be grave or favorable—grave if the urochromogen does not take its place, favorable if it does. 7. The urochromogen reaction is probably of little value as a contraindication to tuberculin treatment and should it be of any value at all, the probabilities are that other factors show such treatment to be contraindicated better and earlier than the urochromogen reaction. 8. This also applies to the diazo reaction as a contraindication to treatment. 9. Should the urochromogen reaction eventually prove of any value in the tuberculin treatment, he believes it will be for a diametrically opposed purpose to that referred to (as a contraindication to beginning tuberculin treatment): in other words, its presence may be a valuable contraindication to discontinuing tuberculin treatment in cases to which all other signs point as arrested. On this point he has not sufficient material as yet to say definitely. He only states that it appears here to be of value, and he hesitates now to discontinue tuberculin in arrested cases which show this reaction.

5. Anaphylactic Food Reactions in Dermatology.—Albert Strickler and Joseph M. Goldberg relate their experiments with the extracts of various foods. They find that the most important factor in the study of anaphylactic reactions is the determination of what constitutes a positive reaction. They conclude that unless a reaction remains for forty-eight hours, it cannot be called positive. The element of time constitutes the most important factor in the determination of a positive reaction. The writers believe that the anaphylactic food reactions, when properly interpreted, are a valuable guide in determining the dietary factors operative in the production of diseases of the skin and that such reactions are specific. In any case in which food stuffs are suspected of being the cause of the pathological conditions present, the cutaneous tests offer a ready means of confirming or negating the suspicion. The tests constitute a basis for the scientific regulation of the diet in such cases. The tests must be carefully and conservatively interpreted in order that one be not deceived by pseudo reactions. A positive reaction to a certain food stuff does not of necessity indicate that the morbid phenomena under consideration are due to this food stuff. Just as a syphilitic patient may develop a skin affection which is unrelated to his systemic infection, so a patient with a positive anaphylactic reaction may develop a cutaneous affection due to other factors than his diet. The writers also believe that further studies in anaphylactic food reactions may shed considerable illumination on the etiology of certain diseases of the skin. Many hundreds and perhaps thousands of patients must be studied before any general deductions can be drawn as to the relation between particular skin diseases and food poisoning.

6. The Relation of Morphine to Postoperative Complications and Immunity.—Benjamin Franklin Davis

states that because of the depressing influence of morphine on the general metabolism, many surgeons have been inclined to blame its use for a long list of disorders appearing the course of and following operations, especially operations done under general anesthesia. With the object of testing the reasonableness of this idea a study was made of the records of 469 patients operated on at the Presbyterian Hospital in Chicago and of the immunity curves (opsonic and lytic) of a series of morphinized animals, particular attention being directed to the possible relationship of morphin to postoperative shock, postoperative ileus (paralytic), postoperative acute dilatation of the stomach, postoperative retention of urine, and immunity. As a result of these studies he finds that the combination of morphine (from one-eighth to one-sixth grain) and atropine (from 1/150 to 1/120 grain) hypodermically before operations is of very little importance so far as the prevention of postoperative shock is concerned, and, in the general run of cases, plays a negligible part in the production of postoperative nausea and vomiting, tympanites and paralytic ileus, and postoperative retention of urine. It has practically no effect on immunity. Morphine alone, preceding local anesthesia, adds nothing to the efficiency of the anesthetic, and causes postoperative nausea and vomiting in 25 per cent of the patients. It deprives the operator of the cooperation of the patient which at times might be valuable. In view of the disadvantages of imposing one powerful medullary depressant, morphine, on another, ether, the preoperative use of morphine should be abandoned. Morphine in one-eighth to one-sixteenth grain doses to an adult of average size, repeated at intervals of not less than six hours, should not be denied patients whose postoperative suffering cannot be controlled otherwise.

8. Drainage of Cerebrospinal Fluid as a Factor in the Treatment of Nervous Syphilis.—Sherman F. Gilpin and Thomas B. Earley ask the question why, if either arsenic or mercury are present in the blood and produce good results in all other forms of syphilis, no such results are obtained in syphilis of the nervous tissue. The answer is given that after the administration of either drug by way of the mouth, skin, or blood vessels, neither drug was to be found in the cerebrospinal fluid. Why? Was it because the choroid plexus would not allow these substances to pass, or if they did pass into the cerebrospinal fluid, it must be by osmosis, and this does not take place because the pressure of the cerebrospinal fluid equals the pressure of the blood in the venous sinuses and capillaries? Was it not reasonable to think that if the pressure was reduced within the cerebrospinal cavity we may succeed in bringing foreign bodies through the capillary walls and thus the direct effect of drugs, such as arsenic and mercury, secured on the nerve tissue itself? Reports are made on three patients who were drained once a week, as much fluid being drained off as would flow. The writers realize that the report of these three cases proves nothing. They know that the time of observation is too short to eliminate the improvement in a case of paresis which may be due only to a remission, but they see that from a clinical and laboratory point of view these three cases are improved and they feel justified in making this preliminary report in order to stimulate work in this field. They have noted marked improvement in mental and physical health with lessening of the ataxic symptoms.

13. Complete Exclusion of the Large Bowel.—Alfred A. Strauss describes his free fascial transplant method, with ileosigmoidostomy for excluding the large bowel, when ileosigmoidostomy or colectomy is considered. It has long been recognized from Roentgen studies that

ileocolostomy alone nearly always results in a certain amount of regurgitation of some of the contents along the colon and cecum, but he believes that a greater part passes by the ileosigmoidostomy along the ileum and follows its normal course in spite of the ileosigmoidostomy. For this reason many surgeons advise colectomy, and for this reason he presents this method. He concludes that this method of excluding the colon by submucous fascial transplant is very efficient and simple. Each end of the bowl can be easily closed off in between five and ten minutes. The operation is absolutely free from hemorrhage, or chance of infection. In the dog at least it does not seem to make any difference whether the closed-off colon is full of intestinal contents or not. The method has the advantage that the lumen can easily be reconstructed by a secondary operation. From the fluoroscopic study, he believes that, while some of the contents regurgitate into the colon, most of the contents found in the colon are due to the food passing by the ileosigmoidostomy along the ileum into the cecum and colon. It seems, therefore, that simple closure of the ileum below the ileosigmoidostomy would suffice in most cases, and this would be safe in man; while, were both ends closed, the appendix must be brought out in a separate wound for appendicostomy, should the colon become distended.

6. Hyperthyroidism as a Cause of the Irritable Heart of Soldiers. C. Percival White and Francis Hernaman-Johnson.
7. Sanitation in Billets and Camps. Adam White.

2. Contributions to the Study of Shell Shock.—Charles S. Myers reports a series of cases under headings which are determined by the most prominent disorders characterizing them, but there were certain disturbances common to all, namely, amnesia varying from complete obliterations of the past to obliviscence of the scenes occasioning and following the shock, severe headache, and a mental condition varying from slight depression to severe stupor. Disturbances of sensation and movement might be absent, or if present, were extremely variable. Twenty-three of these cases of shell shock were treated by hypnosis with the immediate result that 26 per cent. were apparently cured, 26 per cent. showed distinct improvement, 35 per cent. failed to become hypnotized, and 13 per cent. showed no improvement after hypnosis. The recoveries after hypnosis were not necessarily complete or permanent. Despite the slow progress recorded in certain cases, the writer has not the least doubt that the hypnotic treatment which these and other cases received proved a great assistance toward recovery, and would have proved of still greater value if it could have been occasionally repeated later. If hypnosis did nothing else in the treatment of shock cases, it prepared and facilitated the way to complete recovery.

3. Warm Anesthetic Vapors.—Francis B. Shipway points out the defects attendant upon the administration of cold ether by the open method and describes an apparatus by which he administers warm ether vapor. The superiority in this method lies in the fact that there is greater ease in breathing; there is a free airway and complete oxygenation; the loss of body heat is less and hence there is less shock; the patients appear to recover

a little more quickly, and it also seems that lung complications will be a little less frequent with this method. There is no need to warm the ether artificially in very warm weather above the room temperature; in cold weather 85° to 90° F. will give good results. The higher level is better for patients who are feeble or shocked, or for operations which involve much exposure, loss of heat, or much bleeding.

5. The Simpson Light.—W. Douglas Harmer and E. P. Cumberbatch describe the nature, mode of production, and application of the Simpson light. What is known as the Simpson light is the light emitted from an electric arc formed between electrodes of special composition. These electrodes are made by a special process from a mixture of the ores of certain metals, the chief one being a tungstate of iron and manganese, known as wolfram. The application of the Simpson light in therapeutic doses frequently produces an erythema, which appears five or six hours after exposure. A number of cases of various types of disease have been treated with very satisfactory results with the Simpson light, among them being rodent ulcer, lupus, asthma, vaso-motor rhinitis, nasal catarrh and rhinitis, and otosclerosis. The Simpson light seems to stimulate the healing of wounds. Cases of schrapnel wound have been benefitted by the treatment. When disease affects the deep parts or subcutaneous parts there is usually, though not always, no benefit. The method is still in its infancy and it is too early to form any opinion as to its value in the treatment of the different diseases. The first impression obtained, however, is a promising one.

6. Hyperthyroidism as a Cause of the Irritable Heart of Soldiers.—C. Percival White and Francis Hernaman-Johnson report three cases of irritable heart as illustrating the fact that many cases of irritable heart may be explained by a condition of hyperthyroidism, a sort of pre-Graves' condition, the rapid pulse, sleeplessness and tremor being the only signs present. Prolonged strain and shock are recognized as a predisposing cause of exophthalmic goiter and these factors are present in a marked degree in most instances of so-called soldier's heart. The treatment of "irritable heart" in soldiers has been decided of an "expectant" nature, and it would at least seem reasonable that in all cases in which there is a suspicion of hyperthyroidism x-rays should be tried, other suitable measures of course, not being neglected. In the opinion of the author's investigation and treatment on the lines they suggest will alter for the better the prognosis in the type of case known at present as "irritable heart of soldiers."

8. The Domiciliary Treatment of Pulmonary Tuberculosis. G. H. Dart.

1. Researches on Phagocytosis.—H. J. Hamburger presents the results of an extensive study of the influence of various agents, such as small amounts of calcium, iodoform, chloroform, oxygen, and carbonic acid, on phagocytosis. He finds that small amounts of calcium have a stimulating effect on the phagocytes, increasing their motility and promoting chemotaxis, and assumes that this action is based upon a hitherto unknown

specific biochemical property of this metal. Iodoform also increases phagocytosis, by about 30 per cent, and chloroform 1 in 20,000 raises the phagocytosis power 40 or 50 per cent. Similar results were obtained with benzene, camphor, turpentine, alcohol, chloral, fatty acids, and Peruvian balsam. The writer has also attempted to ascertain to what extent phagocytosis depends on the oxygen percentage of the medium, comparing the degree of phagocytosis in common salt solution, treated with air, with oxygen and with nitrogen. The results of these experiments were quite unexpected; it appeared that the phagocytosis was greatest where the slightest amount of oxygen was present. The agreement between these results and the effect of withdrawal of oxygen on the respiratory center is striking. In view of this agreement between phagocytes and the respiratory center the question comes up whether other substances have likewise the same effect on both. Investigating the effect of carbon dioxide on the phagocytes, the writer finds that in weak concentrations carbonic acid increases the phagocytosis and that in high concentrations it has a paralyzing effect. Another substance having a highly stimulating effect on the respiratory center before paralysis sets in is potassium cyanide; it has the same effect on the phagocytes, stimulating in small doses, paralyzing in somewhat larger quantities. It seems all but certain that these phenomena must be connected with the property this substance has of obstructing the oxygen consumption of the cells. The writer states that the more he studies the biology of phagocytes the more he is convinced of their excellence as a simple object for the study of problems of a biochemical nature.

4. Observations on Castellani's "Tetravaccine" and "Pentavaccine."—G. A. Lurie used tetravaccine to inoculate 3000 persons, most of whom he was able to follow for two months after inoculation. Two injections of one-half c.c. Each were given at an interval of five to seven days. The injections were done subcutaneously in the arm. Both the local and general reactions were mild. The writer was able to keep in touch with 2000 of the inoculated persons for two months, and no case of typhoid, paratyphoid A, paratyphoid B, or cholera developed among them. The pentavaccine which the writer used was the typhoid paratyphoid A paratyphoid B cholera Malta fever. The vaccine was obtained from Dr. Castellani and 2000 individuals in the Uskub American Clinic were inoculated with it. The reactions, local and general, was not more severe than in individuals inoculated with the tetravaccine. The author's results with these vaccines are identical with those of Castellani, Mendelson, and Randon. He is of the opinion that these mixed vaccines should be used as a matter of routine in all countries where such diseases exist already or may be imported.

5. A Case of Severe Tetanus Successfully Treated by Antitoxin.—T. P. Kilner cites this case in order to call attention to the fact that insufficient patience and perseverance are exercised on many cases, and that one settles down too easily to the conclusion that all cases with a short incubation period are hopeless from the onset. In this case recovery occurred in spite of well-marked symptoms of the disease and a short incubation period (nine days). Large doses of serum were administered, 46,500 units in all. It was noted that on each occasion when the serum was given the patient's condition became temporarily worse. Gradually there was a relaxation of the muscular spasm and according to last reports the patient was making an excellent recovery.

6. Serological Tests in Dysentery Convalescents.—J. C. G. Ledingham and W. J. Penfold recall that in a

previous paper they announced that the subacute cases of dysentery admitted to the King George Hospital have all been due to infection by *B. dysenteriae* Shiga. Since that time three other subacute cases have been found due to *B. dysenteriae* and two to the Flexner bacillus. Recently a fresh batch of convalescents arrived, and the opportunity was taken to ascertain by agglutination tests with the serums of the cases what proportion of them had suffered from bacillary dysentery. They had now examined the serums of 103 of these cases, the stools in all excepting one being negative as to *B. dysenteriae*, *Entamoeba histolitica*, and typhoid organisms. They found that 49 or 47.5 per cent. of the convalescents had suffered from bacillary dysentery of the Chiga type. Forty-one of the cases showed either one or more of the following protozoa, namely, *Lambia intestinalis*, *Trichomonas*, or *Entamoeba coli*. The positive Shiga agglutination cases were not found to be more liable to harbor the above protozoa than the negative Shiga cases.

Berliner klinische Wochenschrift.

October 25, 1915.

Treatment of Pneumonia with Ethylhydrocuprein.—Loeb treated 30 cases of croupous pneumonia in the course of a year in a Garrison Hospital, making use of chemotherapy. The patients were from 17 to 30 years of age and with several exceptions were robust men. No mild cases are included in the series. Six patients only received symptomatic treatment—the first to be admitted. The remainder received the specific treatment, as a rule alone, but in a few cases with the addition of wine and digitalis. All went to show that the remedy antagonizes sepsis. It should be given early, as soon as chill, fever, pains in chest and cough have appeared, and without waiting for a full diagnosis. The author actively recommends this course to the general practitioner. By the second day a sort of crisis should occur, and in individual cases the crisis is complete. As a rule, however, there is a recrudescence on the third or fourth day so that the drug must be repeated. In one case the recrudescence consisted of the appearance of the disease in the entire opposite lung and approaching heart failure, which was antagonized by stimulants. It was surprising that this patient, with two crippled lungs, respiration of 48 and pulse of 120, nevertheless felt well and had no rise of temperature. The collateral overaction of quinine is sometimes in evidence, and then the author calls off the remedy for 12 hours.

Military Experiences with Infectious Diseases.—Grunmann gives an installment on this subject. He has had a good opportunity to contrast epidemic cerebrospinal meningitis in civil and military practice. In the former he had never seen a roseola or petechial rash, but his soldiers presented the latter in a highly generalized form, as seen also in petechial typhus. He cites an opinion to the effect that the disease in question cannot be a modern one, dating from 1805, as is claimed; and that it must have been merged in the epidemics of typhus or in the so-called petechial fevers of typhus type. In some of his soldiers the petechiae were by far the most striking clinical phenomenon. They even appeared on the palms and soles and conjunctivae. They appear at the very outset of the disease, whereas in typhus they are seen somewhat later. In regard to the nature of the meningeal disease this consists of a rise of intracranial pressure due to increase of cerebrospinal fluid. This causes the headache, slow pulse, vomiting, vertigo and disturbances of innervation. Lumbar puncture relieves this train of symp-

toms. Other phenomena of this causation include increased vasomotor excitability, as shown incidentally by the frequency of dermographism. Herpes facialis was so typical that the author examined the contents of the vesicles for meningococci, but the results were negative. Changes in the intracranial tension due to the relative amount of cerebrospinal fluid are responsible for the irregular course of the disease. Internal hydrocephalus tends to appear in protracted cases. Intraspinal injections of serum may aggravate the symptoms, doubtless from the increase of tension caused. Subjectively, headache is the worst symptom, but it yields to lumbar puncture and morphine.

Summer Diarrhea.—Marx considers these from the viewpoint of a bacteriologist. In the Western battle front diarrhea appeared last June, and was of a somewhat dysenteriform type. In a small per cent. only were the Y and Flexner bacilli found; the great majority showed no exogenous pathogenic cause, and the author does not regard the average summer diarrhea as an infectious entity having a specific cause, as is the case with dysentery or cholera. He is inclined to hold the bacillus coli responsible, the harmless and even benevolent saprophyte having for the nonce developed a pathogenicity. We must never forget that bacteriology is before all a subdivision of botany, and the teachings of the latter must hold good for it. If we had borne this in mind less time would have been wasted in studying alleged mutation forms of bacteria. The *B. coli* is remarkable for its variability, which is due to the special nutrient media upon which it is cultivated. But every plant shows variability under such conditions. These normal denizens of the intestine are chiefly atypical, and the more nearly normal the stools the fewer the number of atypicals. If a normal diet is varied—for example, should an individual eat a lot of unripe fruit—a change is seen in the coli form, which may be regarded as bordering on the pathological. How far removed is the latter from the dysentery bacilli? Of these only the Shiga forms a definite species. The Y and Flexner germs are much less satisfactorily differentiated. Botanically, they do not constitute "good species." In dysenteric stools we see species and subspecies, varieties and subvarieties. These we can cultivate and christen at will. The author is inclined, for simplicity's sake to see in these only phylogenetic offshoots of a *Protabacillus coli*. These variations are of the present, not the past, and occur continuously. In this wide significance must the hygienist regard bacteriology. Variation is a function of diet and dietetics is also a subdivision of hygiene. There should be an integration in bacteriology as a reaction from overstudy of variations.

Protective Inoculation against Typhoid.—Professor Hueppe mentions the cases of soldiers who had been successfully inoculated with fresh virus against typhoid, with two repetitions. The blood was rendered rich in immune bodies with high agglutinating power, yet they contracted clinical typhoid in a severe form and with fatal outcome. These soldiers who were fighting in the Carpathians were subjected throughout to prodigious physical activity and the native resistance must have been reduced. There is also a suspicion that something besides the usual Eberth's bacillus may have been active in the production of the disease. Nevertheless, even these Carpathian troops who derived so little protection, may have profited as a whole by inoculation because the incidence of typhoid was less

than could have been anticipated. In winter and especially during thaws when the troops were repeatedly chilled and at the same time underfed there was noticed an outcropping of various infectious diseases, to wit, influenza, pneumonia, meningitis, etc. The appearance of typhoid at this juncture, as diagnosed chiefly by the continued fever and enlarged spleen, may, from analogy, have been an atypical form of influenza. The diagnosis of typhoid appears to have been clinical and not bacteriological.

Local Treatment of Meningeal Syphilis.—Gennerich sees no advantage in the intraspinal exhibition of salvarsanized serum, in comparison with injections of salvarsan *per se*, although not denying that later returns may change this view. The time is now ripe for three-year statistics of cases of meningeal syphilis treated with salvarsan. By the term meningeal syphilis the author denotes several distinct lesions, viz., a histological affection (relapsing meningitis), syphilis cerebrospinalis, and incipient metalues. In confirmed metalues only the good general condition of the patient justifies hope of benefit from treatment. The ordinary combined treatment—salvarsan and mercury—as applied to constitutional syphilis, cannot exert any notable therapeutic action on meningeal lesions. That certain histological alterations in the pia are responsible for the eventual development of metalues is not due to any biological alterations in the spirochete, but results from the inaccessibility of this membrane to ordinary internal medication. The membrane should be the more accessible through the cerebrospinal fluid but here two inhibitory conditions assert themselves. First the spirochete may be just beyond access, and second, all depends on the proper concentration of salvarsan in the cerebrospinal fluid; by proper is meant suitability for the individual case. If the treatment does not benefit, it is quite possible for it to irritate. In the cord, salvarsan in improper concentration may even cause myelitis. The author has a long list of indications for dose based on symptoms, the results being uncertain at best in contrast with ordinary cerebrospinal syphilis in which they are often brilliant. In the present study the author dwells but casually on the so-called histological recurrent or relapsing inflammation of the pia. To merit this distinction, in the absence of autopsy finds, there should be a special cytological picture of the cerebrospinal fluid, which is not described in the article.

Results of the Mesothorium Treatment of 100 Cases of Cancer of the Uterus.—Baisch has used radium and mesothorium on these growths since February, 1914, and has controlled 100 cases in this manner during a fifteen months interval. Clinically three types of disease were treated, as follows: completely inoperable, barely operable, readily operable. The latter class does not comprise beginning cases, such as might be accidentally stumbled upon. Of the inoperable 43 cases treated by radiation, but one may be termed cured; of the remainder 20 have ended fatally, while 22 have not been improved. The cured case, isolated though it be, is a striking example of what mesothorium can do. In numerous other cases the remedy caused amelioration of symptoms, and delayed the outcome. Bleeding and fetor were checked and some of the women were able to return to their work. In general, it may be safely asserted that mesothorium (including radium) is the best known palliative. The second group of "not yet inoperables" was made up of 20 subjects who "stood on the borderline of operability." In 50 per

cent. of these cases recovery ensued, while 4 patients are dead and 6 are not improved. The conditions of recovery differ from those in which surgery is the treatment, as recurrence after eighteen months of quiescence following mesothorium treatment is not likely to happen. There remain 37 cases of readily operable cancer in which mesothorium was the treatment. Of this number 28 are apparently cured, while there have been 5 deaths and 4 negative results.

Collargol in Sepsis and Acute Rheumatism.—Reichmann, who had good results several years ago, has within the past year used the remedy systematically in sepsis and in six cases of the latter has obtained from recoveries. The first case was one of proved streptococcus sepsis in a child aged twelve, following measles. A hematogenous meningitis was one of its manifestations. Collargol was injected with no decisive result. After a brief favorable course of the disease a high fever and polyarthritides developed. One wrist was about to suppurate when collargol was given in a vein with astonishing results. Renewal exacerbations made several other injections necessary but patient recovered cleanly. In the second case in a young child an otogenous meningitis first developed. The occurrence of bacteria in the blood was very doubtful but collargol was given for supposed bacillemia, and seemingly with the best consequences. The power of the drug over the fever curve was undoubted. The third case treated was of obscure nature. One lower extremity was swollen to double the natural size, there was marked anemia, the nutrition was miserable, and a high fever was present. Blood cultures showed staphylococci and collargol was given by a vein. The temperature curve responded decisively. In the belief that pernicious anemia existed both salvarsan and Fowler's solution were given without much influence on the blood count. The femoral thrombosis gradually underwent involution. The fourth case is very briefly described. The bacteriemia was hypothetical, the supposition being that a septic process had developed after measles in a two-year-old child. In the two fatal cases there was evident bacillemia from staphylococci.

Direct Injections into the Heart in Desperate Conditions.—Szubinski relates three cases of intracardial injections, which were made to replace the ordinary intravenous injection in impending heart failure. A preparation of digitalis was used along with suprarenin. In addition intravenous and subcutaneous injections were made in the hope of maintaining the gain. The first of the soldiers treated had both legs shattered and had bled for two hours before transport from the field. There was no response to ordinary remedies. The pulse and respiration showed that death was imminent. The intracardiac injection caused a sudden brief rally—two or three minutes long—after which the old picture reappeared. The second patient was badly shot up with protrusion of most of the intestine through four openings, and shot fractures. The intestines were hastily replaced and the openings sutured. The patient seemed hopelessly shocked. There was a rally after the intracardiac injection and the patient became restless and partly sat up. He survived ten hours under ordinary subcutaneous injections of caffeine and camphor with Murphy's rectal drip. In the third case was one of wound of the head. There was Cheyne-Stokes breathing. Strophanthin and suprarenin were injected. There was a brief rally with death in fifteen minutes. It is possible that now and then these injections will save life.

Book Reviews.

POTTER'S COMPEND OF HUMAN ANATOMY. Revised by D. GREGG METHENY, M.D., L.R.C.P. and S. (Edin.), L.F.P.S. (Glasgow), Associate in Anatomy, Jefferson Medical College, Philadelphia. Eighth edition, with 139 illustrations; also numerous tables and 16 plates of the Arteries and Nerves. Price, \$1.00. Philadelphia: P. Blakiston's Son & Co.

THIS well known compend is now in its eighth edition, and the work is said to have been rewritten. We have been unable to find in it any account of the spinal column, the intercostal veins, the patella. On pages 189 and 190 "foramina" occurs no less than eight times; but whether this is due to the eccentricity of the author or that of the printer we do not know. On pages 243 to 255 the "tables" and "plates" are most perversely arranged; thus, the student while attempting to master the seventh cranial nerve is confronted with a good diagram of the fifth nerve; and the diagram of the seventh nerve faces the description of the ninth, tenth, and eleventh nerves. For some dozen pages this annoying condition persists and reduces the value of the illustrations very much indeed. This is an important feature and one which cannot fail to make the book unpopular with the only class of reader likely to use it.

DIAGNOSTISCHE UND THERAPEUTISCHE ERGEBNISSE DER HIRNPUNKTION. Eine Kritische Studie, von Dr. WALTER PINCUS, Spezialarzt für Chirurgie. Berlin: Verlag von August Hirschwald, 1916.

THIS work was completed in 1914 and covers the work done since the methodical introduction of cerebral puncture in 1904. It is very largely a volume of case histories and should be of notable value to those who propose to devote themselves to cranial surgery. The chief affections considered are hydrocephalus and meningitis serosa, cranial hemorrhage, cerebral abscess and purulent meningitis. The diagnostic and therapeutic uses of puncture, the technique, and the dangers of hemorrhage, infection, and sudden change in blood pressure are fully considered. There is a brief closing chapter on negative puncture.

DISEASES OF INFANTS AND CHILDREN. By HENRY DWIGHT CHAPIN, A.M., M.D.; Professor of Diseases of Children, New York Post-Graduate Medical School and Hospital; Supervising Physician of the Children's Department, New York Post-Graduate Hospital; Consulting Physician to the Willard Parker Hospital; to the Randall's Island Hospital; to St. Agnes' Hospital, White Plains; to Convalescent Home for Children, Sea Cliff; and to the Hackensack Hospital; Ex-President of the American Pediatric Society; and GODFREY ROGER PISEK, M.D., Sc.D., Professor of Diseases of Children and Attending Physician to the New York Post-Graduate Medical School and Hospital; Professor of Diseases of Children, University of Vermont Medical College; Visiting Physician to the Willard Parker and Riverside Hospitals; Pediatricist to the Park Hospital; Consulting Pediatricist to the Darrach Home for Children and to the Union Hospital, Portchester. Third Revised Edition, with 179 cuts and twelve colored plates. Price, \$3.25 net. New York: William Wood & Company, 1915.

THE value of this book as a teaching manual has been greatly enhanced by the greater compactness of the volume in its new form, with its 578 pages of thinner paper instead of the 636 pages of the previous edition, and with the description of the rarer conditions in a smaller type. At the same time the text has been thoroughly revised and considerable new matter has been added, such as protein-milk feeding, special diet lists for older children, the action of catalyzers, the Schick and luetin tests, and mental tests especially adapted for the early months of life. In addition to the numerous cuts there are twelve excellent colored plates. The volume may be recommended without reserve as a reliable and up-to-date manual of pediatrics.

THE CLINICS OF JOHN B. MURPHY, M.D., at Mercy Hospital, Chicago. Vol. IV, No. IV, August, 1915. Octavo of 216 pages, with 40 illustrations. Published bi-monthly. Price, per year, paper, \$8.00. Philadelphia and London: W. B. Saunders Company, 1915.

IN this number of the Clinics the usual initial discussion in detail of some subject in the realm of surgical diagnosis has been omitted and the entire volume is

given over to the discussion of clinical cases, thirty-two in number, covering surgical conditions in various parts of the body, from intracranial lesions to fractures of the bones of the foot. Among the most interesting cases considered are two of carcinoma of the lower lip and one each of tumor of the parotid gland, metastatic thymus tumor of the male breast, and acute hemorrhagic pancreatitis.

SYPHILIS AS A MODERN PROBLEM. By WM. ALLEN PUSEY, M.D. Professor of Dermatology in the University of Illinois. Price, 50c. cloth; 25c. paper. Chicago: American Medical Association, 1915.

WHEN a problem is brought out into the daylight, there begins to be some hope for its solution. Dr. Pusey's book is one of many attempts now being made to have the lay public face the problem of syphilis honestly, understandingly.

The book is a clear, dignified presentation of the facts. It gives first a history of the disease, how it was carried back to Europe from America by Columbus' sailors, and of its rapid spread over the entire world. The presentation of the course of the disease, in both the acquired and hereditary forms is not too technical. The chapters on the Prognosis of Syphilis, Syphilis and Marriage, and the Prophylaxis of Syphilis are those for which the book is really written, and will command the attention and thought of those who read. These chapters make clear how and why the problem must be attacked from its social aspect. The book should be widely read, and physicians will do well to increase its circulation as much as possible.

WUNDHEILUNG MIT ÄTHERISCHEN OELEN, von Dr. DANIEL WAGNER. Oberarzt des allgemeinen Spitals in Békéscsaba. Price, 2.50 M. Berlin und Wien: Urban und Schwarzenberg, 1915.

It is perhaps enough to say of this work that it describes a partially secret remedy (the ingredients are given without percentages or modes of combination), which is for sale under a proprietary name, or rather series of names, for it is recommended for external and internal uses, the former including a liquid soap.

NEUE UNTERSUCHUNGEN ÜBER FLEISCHEXTRACT. Von Dr. LEBBIN, Nahrungsmittelchemiker. Price, 1.60 M. Berlin: August Hirschwald, 1915.

A praiseworthy attempt to answer the perennial question "when is a meat extract not a meat extract?" and "why?" Some of the most famous trade products fall far short of a practicable standard in certain of their ingredients.

DIE GEMÜTSBEWEGUNGEN, ihr Wesen und ihr Einfluss auf körperliche, besonders auf krankhafte Lebenserscheinungen. Eine medizinisch-psychologische Studie von Dr. C. LANGE, Professor der Pathologie in Kopenhagen. Zweite Auflage besorgt und eingeleitet von Dr. H. KURELLA, Nervenarzt in Bonn. Mit 1 Abbildung im Text. Price, M. 1.80. Würzburg: Kurt Kabitzsch (A. Stuber's Verlag), 1915.

THIS is a translation of the Danish physiologist, C. Lange's work on the Emotions, first published in 1885. The first edition of this translation appeared in 1887. This second edition has been carefully revised with but few changes; and certain additions contained in the French edition of Lange's work have been included.

It deals with a physiological theory of the constitution and conditioning of the emotions, their nature and influence over normal and pathological phenomena of life. Quotations from and discussions of the first edition of this book are to be found in William James's writings. (Principles of Psychology, Henry Holt.) The James-Lange Theory takes into consideration that bodily changes constitute a part of all strong emotional experiences and are in fact the real essence of the emotion. According to one, emotion is the cause of which the physical manifestations are the effects, and according to the other the physical manifestations are the cause of which the emotion is the effect.

S. WEIR MITCHELL, M.D., LL.D., F.R.S., 1829-1914. Memorial Addresses and Resolutions. Philadelphia, 1914.

THIS work is a collection of eulogies of an illustrious man by a number of lifelong friends and admirers, who are themselves distinguished. It is well that the record of work accomplished and an appreciation of the character and ability of so distinguished a member of our profession should be put in permanent form as a contribution to the history of medicine.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twenty-Eighth Annual Meeting, Held at Cincinnati, Ohio, December 13, 14, and 15, 1915.

THE PRESIDENT, DR. BACON SAUNDERS OF FORT WORTH, TEXAS, IN THE CHAIR.

High versus Low Degrees of Heat as Palliative Treatment for Advanced Cases of Cancer of the Uterus.—Dr. HERMAN J. BOLDT of New York City claimed for the galvanocautery treatment, first brought to his notice by the late Dr. Byrne, Brooklyn, New York, that it gave more satisfactory results in such cases than any other method of treatment with which he was acquainted, so far as his personal experience went. Radium and x-ray, even with the newer methods, had not been so satisfactory. The intravenous injections, or the intramuscular injections of various medicaments recommended for experimentation from time to time, and from which improvement or even cures had been reported, had not in his hands had any discernible good effect. Although the results that one saw reported from the use of radium were not short of miraculous, unfortunately, he had not been able to verify such miracles. Galvanocautery treatment had stood the test of time and it had been proved by clinical experience that patients properly trained thereby lived longer, and were free from distressing symptoms. It was a comparatively safe therapeutic agent when used in suitable cases; that was, for such patients in whom the disease had not already advanced too far, so that the bladder and rectum would probably not be injured by a thorough application. The claim of Dr. Percy that the application of lower degrees of heat, so low that a carbonization of the tissues was not caused, and applied for a much longer time, had a deeper destructive influence, appealed to the profession, and he gave it a thorough test for two years, although he did not see in any case a superior clinical advantage. Recently he had shown it to be a fallacy by an autopsy and a careful study of the tissues from a woman who had died eight days subsequent to the heat application for two and a half hours, according to the rules laid down by Dr. Percy. Here it was illustrated that directly beyond the cauterized zone there were actively proliferating cancer cells. Dr. Percy's experimentation was done on dead tissues and the destructive action did not penetrate beyond the superficial structure. He had proved beyond a doubt that the application of heat so low as not to char the tissues, although the desiccation method be used precisely according to the directions of Dr. Percy, was of no more value in hindering cell growth in the depth of the tissues than high degrees of heat, as were formerly and were now again used by him. The technique advocated by him had, moreover, the advantage of being able to do the cauterizing in from twenty to thirty minutes, and he believed that the destruction of tissues was carried deeper, leaving only a shell of the cervico-uterine structures. The degree of heat employed by him was much higher than that which was advocated by Dr. Byrne. While the electrode was at a cherry-red heat when applied to the tissue by Byrne, this heat soon diminished; but he turned on more current and kept it at that degree while it remained in contact with the tissue, and when a fairly thick layer of carbonized structure had been produced, more current was turned on to raise the heat of the dome electrode to a light red. The electrode must be taken off to make frequent examinations during the process of burning, to determine how much tissue had been burnt out, and to burn off the layer of carbon accumulated upon the electrode. It required from one to two weeks for the carbonization eschar to be thrown off, and then there was a slight sanguineous oozing which might be controlled by the use of acetone, or a strip of styptic gauze might be packed into the cavity. But what was still better was now to resort to the desiccation process by the slow heat method. It was now not necessary to use the heat more than twenty to thirty minutes and now no carbonization must be caused; but one must be careful not to use too much pressure with the electrode, since, if the first treatment had been properly done, only a shell of cervicouterine structure was left. Opening of the abdomen was not necessary for the second cauterization or rather desiccation. For additional

after treatment the use of radium was desirable since there was no doubt that it was of benefit to some cases of cancer. A capsule containing 75 mg. might be placed in the cavity and held by a gauze tampon for twenty-four to forty-eight hours. This was to be repeated once a week for several weeks. No patient, after the cautery operation had been done, should be permitted to be out of constant observation until the carbonized eschar had been completely thrown off and danger of a possible secondary hemorrhage dismissed. The ligation of the internal iliac arteries, as originally advised by Dr. Pryor, and oophorectomy as a preliminary step, were good procedures. He had been able to verify the claims made for the ligation of the arteries, in that it lessened the bleeding and the discharge in the cases of patients with so-called carcinoma of the uterus.

Moschowitz's Operation—Inguinal Route for Femoral Hernia.—Dr. J. D. S. DAVIS of Birmingham, Ala., stated that if the same surgical factors were utilized in femoral hernia that are used in inguinal hernia, relapse would be rare. There were certain erroneous impressions regarding the crural route for femoral hernia that gave rise to disaster. The opinion was prevalent that the repair of femoral hernia by the thigh route was a simple operation; that the technique did not require anatomical exposure of the field of operation and that recurrence was rare. The statement that femoral hernia did not tend to recur after high ligation of the sac was without foundation, even with closure of the ring by the operation of Bassini or Fabricius with high ligation of the sac, a funnel-shaped projection of the peritoneum was always left which constantly tended to recurrence. If the same precautions were resorted to in femoral hernia that were utilized in inguinal hernia (high ligation of sac, secure closure of the internal ring from above, and aseptic wound healing) relapse would be as rare as in inguinal hernia. The inguinal route or approach rendered resection and anastomosis a very easy procedure compared to a resection in an operation by the crural route. The supplementary abdominal incisions so often necessary in resection when the crural operation was made, need not for a moment even be considered when the operation was made. When femoral hernia was attacked by a high incision (inguinal route) anatomic exposure of the femoral ring could be made from above, bringing into view Cooper's ligament, which was utilized in the closure of the ring. In the operation for the cure of femoral hernia by the inguinal route, the skin incision was not unlike that made for the Bassini operation, except when the sac was found adherent, when the incision might be extended down into the thigh so as to give room for extirpation of the sac. The next step in the operation was that of dividing the aponeurosis of the external oblique. The upper flap of the external oblique aponeurosis, the internal oblique and transversalis were held up by a retractor while a second retractor was placed under the lower flap of the external oblique aponeurosis, which retracted downwards, bringing Poupart's ligament into view. A tape or piece of gauze was passed beneath the round ligament or spermatic cord and used to retract the round ligament inwards, and in case of a male, the spermatic cord was to be retracted outwards, which gave a very good exposure of the field of operation, with its floor covered by the transversalis, a thin layer of fascia just over or next to the peritoneum. The transversalis was bluntly divided along the line of the border of Poupart's ligament, then picked up by the retractors and held with the other tissues, upwards and inwards, and outwards and downwards. This retraction brought the peritoneum with the constricted neck of the sac into view. The retractor was removed from the lower and outer flap to show the lower cut surface of the transversalis fascia attached to Poupart's ligament and its relationship to the peritoneum. If the deep epigastric artery should run an anomalous course, it would at this stage come into view, which might be retracted or cut between ligatures. The sac was retracted with its contents, or if this was impossible Gimbernat's ligament which forms the sharp margin of the constricting ring, might be cut with a blunt pointed herniotomy knife. The ligament was in full view, which made it practically impossible to encounter an anomalous obturator artery. If so, it was in view, and the hemorrhage could be promptly controlled; but in an operation by the crural route or by the thigh, Gimbernat's ligament must be cut blindly, endangering the obturator artery, from which a hemorrhage might occur that was very hard to control, or the sac might be opened just where it converged from

the neck, through which opening the hernial contents might be retracted and placed in the peritoneal cavity, and held by a sponge or pack. If the hernial contents were adherent to the sac loose in its bed the sac and contents could be pulled out of the hernial bed, converting a femoral hernia into an inguinal hernia, which made it convenient and an easy task to deal with sac and contents. If the sac was adherent to its bed a pair of artery clamps should be introduced down to the lowest point in the sac, then closed and withdrawn. If the sac did not evert on account of adhesions to the bed in which it lay, the lower skin flap might be retracted down over the thigh, or the inguinal incision might be extended downward on the thigh over the hernial protrusion, thus enabling the operator to dissect the sac free of adhesions. The sac was tied off and transfixed beneath the transversalis, and internal oblique muscles. It was tied off sufficiently high, and drawn up under transversalis and internal oblique muscles, so as to provide against leaving a protrusion or dimple or funnel-shaped projection of the peritoneum and safeguard against relapse. The inner and upper flap was retracted inwards and upwards, and the outer and lower flap outwards and downwards which exposed to full view the femoral ring bounded externally by the external iliac vein, femoral and internal epigastric arteries; anteriorly by Poupart's ligament; internally by Gimbernat's ligament covered by a reflection of the transversalis fascia, and posteriorly by Cooper's ligament. With a small curved blunt-pointed needle, threaded with catgut suture No. 2, Cooper's ligament which could be seen—a dense, tough, white, glistening, fascial membrane—covering the horizontal ramus of the pubis, was pierced just internal to the iliac vein, and then the needle was carried through the lower flap of the transversalis fascia, and the edge of Poupart's ligament. Two or three sutures were now similarly placed internal to the first. The last one and the most internal suture picked up Gimbernat's ligament. Tying all these sutures approximated Cooper's ligament and Poupart's ligament which effectually closed the hernial orifice. The operation was now to be completed as if an inguinal hernia by the Bassini method. The internal oblique and transversalis muscles and the flap of the transversalis fascia were sutured en masse to the overhanging portion of Poupart's ligament, making a bed for the spermatic cord in the male. The round ligament in the female was never transplanted. The external oblique was next closed over the cord—lapped or imbricated—and the skin was closed with buried catgut No. 1 suture or with a silk or horsehair button-hole suture.

A Clinical and Experimental Study of Postoperative Ventral Hernia.—Dr. WILLARD BARTLETT of St. Louis thought that the causes of postoperative ventral hernia were incisions in defiance of anatomical and physiological principles, improper wound closure, needless drainage and tamponade, postoperative increased intraabdominal pressure and wound infection. Experiments on dogs produced no sign of hernia where one layer was preserved. Hernia resulted where a defect was produced in all layers, except skin or skin and peritoneum, successful repair of those being made by inversion of the opposite sheath, overlapping of both sheaths, or fascia lata transplantation. Complete defects were immediately repaired with transplants of fascia, sheath transplants, or the reflection of opposite sheaths. To restore the abdominal wall in those hernias, only one to three fibrous layers were depended upon. The experiments proved that postoperative hernia depended upon two factors, namely, a weak wall and hernial tendency. In the human subject the hernial tendency was corrected preoperatively by reducing intraabdominal fat and intestinal contents, with rest in bed, liquid diet, and free catharsis. The best postoperative procedure left the sac intact, utilizing the sac wall and scar tissue, but, if necessary, the abdominal contents might be reduced. If there was undue tension on the reconstructed wall, or interference with the movements of the lower ribs, failure was sure. Choice of operation depended upon the site of the lesion, the size of opening and hernia, the condition of surrounding tissue and general condition of the patient. The varieties of operation were overlapping, reconstruction, flap inversion, filigree and free transplantation. Kirschner prefers fascia lata because of its easy accessibility and quantity, its strength, inelasticity, adaptability, and tendency to heal in. One reinforcing suture line outside or one inside and outside, a complete defect, practically insured success. The after-treatment was of vital im-

portance, dealing chiefly with meteorism or straining of any kind. In the clinical series of seventy-eight operations, seven results were not known, two treated with filigree were failures, four recurred after the overlapping method, while the others were all complete cures.

Adenomyoma of the Round Ligament and Incarcerated Omentum in an Inguinal Hernia Forming One Tumor.—Dr. THOMAS S. CULLEN of Baltimore reported his first case of adenomyoma of the uterus in March, 1895, and since then he has been much interested in adenomyomata. In 1896 he reported his first case of adenomyoma of the round ligament. Since that time a number of adenomyomata of the round ligament had been detected. When analyzing the umbilical tumors recorded in the literature he encountered quite a number that had been variously diagnosed. Those tumors were found only in women, tended to swell at the menstrual period, and occasionally discharged a little blood at the period. On section some of them contained small spaces filled with old blood. Those tumors proved to be adenomyomata of the umbilicus. More recently adenomyomata of the rectovaginal septum had been noticed. Cuthbert Lockyer and Jessup had each reported two cases, and the author had four. In 1889, Dr. Wm. W. Russell reported a most interesting case where a large amount of uterine mucosa was found in the hilum of the ovary. We might find adenomyoma of the uterus, the round ligament, the rectovaginal septum, or in small umbilical tumors. Nearly three years ago he operated on another adenomyoma of the round ligament. The patient was forty-three years of age, and complained of a lump in her groin for several years. This was very firm and appeared to be cystic. It was about 4 cm. long, 2 cm. broad and somewhat lobulated. She also complained of pain in the appendix region. He first made an incision and found the rectum firmly adherent to the left ovary over a considerable area. The adhesions were gradually loosened and the raw area on the bowel closed. He then examined the omentum and found that it passed down through the hernial opening near the right internal inguinal ring and then directly out into the adipose tissue of the anterior abdominal wall. The omentum was cut off at the internal ring, tied, and pushed out of the way. The extraperitoneal portion of the omentum was left *in situ*. The peritoneum over the appendix which showed evidence of old inflammation, had adhesions passing off from it in various directions. After closing the abdomen he made an incision over the tumor in the right inguinal region. The tumor was adherent to the skin. The skin was dissected back and the mass cut away from the fascia. There were numerous cysts, some filled with clear colored contents, others with slightly turbid fluid, and quite a number with chocolate-colored fluid, strongly suggesting adenomyoma. After dissecting away the lower portion of the tumor, which was also adherent to the fascia, he now lifted up the omentum from the hernial opening. The hole left near the internal ring was slit-like in form and about 1 cm. long and 4 cm. broad. It was closed with kangaroo tendon. To dissect back the fascia and do an orthodox operation was out of the question because of the large defect that would have been left. At most points good firm scar tissue existed. He closed the wound with through-and-through silkworm gut sutures. Accurate skin approximation was made with fine, black silk. The lower angle of the wound was drained with protective. The patient made a good recovery.

Early Tuberculosis of the Cervix.—Dr. CULLEN also reported this case. The patient was a colored woman, twenty-five years of age, who complained that fecal matter had been discharging through the vagina for two years. She had been married six years but had never been pregnant. Her menses began at 19 but for the last five years she had had no periods. At operation the resident gynecologist, Dr. J. C. Neel, found the uterus in retroposition and the bladder adherent to it above the internal os. The sigmoid was adherent to the vesicouterine flexion, just above the level of the internal os. The right tube and ovary had become twisted over the anterior surface of the uterus. The bladder and tube were freed and the fistula between the vagina and rectum cut across. The small opening in the sigmoid was closed. The uterus, which contained several myomata, was removed, a complete hysterectomy being done. The laboratory diagnosis was bilateral follicular salpingitis, uterine myomata, tuberculosis of the endometrium, and tuberculosis of the cervix. Tuberculosis of the cervix was rare, and such an early stage as was here depicted he had never seen before.

President's Address: The Great Professional Problem

of the Present Decade.—Dr. BACON SAUNDERS of Fort Worth, Texas, said that many private sanatoria were conducted on the highest scientific plane in the most sanitary, efficient, and ethical manner, and were, therefore, beyond the pale of criticism. But, unfortunately, it was also true, be it said to the everlasting shame of men and women boasting of the insignia and parading in the habiliments of medicine, that probably somewhere from 30 to 50 per cent. of the privately-owned and secretly operated pseudo-sanatoria were hotbeds of dishonesty and veritable culture fields of immorality. In short, fit hibernating places for his satanic majesty and all his devilish hosts. He wondered if those in power realized what a travesty on public benefaction it was when in almost every State of this glorious Union of ours, anybody, no matter who, so long as he went by the sobriquet of "doctor," could get a charter under the great seal of the State, for anything and no questions asked, provided the bantling was called by the name of "sanatorium." In the fullness of time, when the great heart of medical men really and sincerely beat for human welfare and happiness, there would come some power whose duty it would be to see that that disgraceful state of affairs was made impossible.

Results of Operations for Exophthalmic Goiter.—Drs. E. STARR JUDD and J. D. PEMBERTON of Rochester, Minn., selected for study cases that had been operated on more than five years ago (1909) for exophthalmic goiter, because it was difficult to say when a case of exophthalmic goiter had been cured. Their report embraced 121 cases which they were able to trace by repeated examinations or correspondence. This study revealed the fact that about 46 per cent. of the cases operated more than five years ago had remained entirely well and showed no evidence of their old symptoms; about 23 per cent. were practically cured, although a slight trace of their old trouble persisted or temporarily returned under severe nervous strains, etc.; between 4 and 5 per cent. were somewhat improved by operative interference, while about 5 per cent. reported that they had received no benefit. The series did not include merely selected cases, but embraced all the cases operated in 1909 that they were able to keep in contact with either by subsequent examination or correspondence. They ligated the superior thyroid vessels in some patients simply as a preliminary measure and advised them to return in three weeks for thyroidectomy, and in some instances so much improvement followed this procedure that they did not come back; however, they observed that late recurrence of symptoms was more frequent among patients who had simply been ligated than among those who had had resections of the thyroid gland. Frequently, in mild cases ligation of the superior thyroid vessels was all that was necessary. Several patients who had resection of the gland, had since reported the birth of normal children; one woman had borne three normal children. Seven of the twenty-one patients who died were never able to leave the hospital and were extremely toxic at the time of operation. The remaining fourteen patients lived an average of 14.1 months after operation, and death probably ensued on account of the irreparable damage in the heart, liver, and kidneys, due to continued intoxication. A more general education of the public resulting in earlier interference in those cases would greatly increase the percentage of cures.

Unilateral Hematuria Associated with Fibrosis and Multiple Microscopic Calculi of the Renal Papillæ.—Dr. R. L. PAYNE, JR., of Norfolk, Va., referred to previous experimental work by him in which the chiefly developed vascular lesions were eliminated as a cause of symptomless unilateral renal hemorrhage. He reported a case of symptomless unilateral hematuria in which bisection of the kidney showed macroscopically a normal cortex or parenchyma, but every papilla presented a cherry red appearance so typical of angioma. The kidney was removed and careful microscopic studies disclosed an absence of pathological findings in the cortex or parenchyma proper, but the papillæ showed definite chronic inflammatory changes. These changes consisted of (1) An overgrowth of connective tissue. (2) Multiple microscopic calculi. (3) Dilated capillaries with the small calculi in close apposition or the capillaries surrounded by the connective tissue proliferation. (4) A network of dilated capillaries on the surface of the papillæ, many of which were ruptured with free blood escaping. These numerous, though small, varices, were evidently the source of the hemorrhage and the inference was that the numerous calculi, aided by the connective tissue they had originated, suc-

ceeded in causing an obstruction to the venous return with a subsequent dilatation of the capillaries, and resulting varicosities.

Pancreatic Cyst.—Dr. JOSEPH RANSOHOFF of Cincinnati presented the history of a case of pancreatic cyst, with what he believed to be the unique symptom of hematuria. The tumor was situated in the left upper quadrant, projecting into the loin, distinctly fluctuating and of slow growth. When first seen it was nearly as large as an adult head. Cystoscopic examination showed a bloody stream of urine issuing from the left ureteral orifice. Indigo-carmin injection demonstrated equal function on the part of the two kidneys. Ureteral catheterization and radiographing of the renal pelvis were refrained from an account of the weakened condition of the patient at the time of examination. The barium bovilac injection per rectum showed the colon normal. A diagnosis was made of cystic sarcoma of the left kidney. Lumbar exposure of the kidney showed it to be normal. Median incision then displayed the cyst of the pancreas, projecting between colon and stomach with the spleen six or eight times its normal size. The hematuria disappeared after the operation. The pressure of the pancreatic cyst on the renal and splenic vein had produced the hematuria and the enlargement of the spleen. The pancreatic matter of the cyst was demonstrated by the presence of the three pancreatic ferments, alkaline, proteinase, amylase, and lipase. There were also little masses of saponified fat. So far as he knew, the case was unique, since search of the relevant literature had failed to show a similar case.

Dr. FRANCIS R. HAGNER of Washington, D. C., said there was one point we ought to consider, and that was, in splitting a kidney from pole to pole many of us did not realize we were doing a partial nephrectomy on that patient. He had had two or three patients who had had that done some ten years previously, and the destruction of the kidney from that incision was really remarkable. Possibly one-fourth or even more of the kidney was destroyed by that incision. As to Dr. Ransohoff's case, he believed the hemorrhage was due to pressure on the renal vein. Recently he had a patient upon whom a prostatectomy was done three years ago, and he came back with hemorrhage from the left ureter. He catheterized the ureter and found a stricture just at the entrance of the ureteral orifice, while on the other side, the urine was clear. This stricture was dilated and a catheter passed up to the kidney. The urine was still clear, and the next day hemorrhage stopped. This patient had had three recurrent hemorrhages in that way, but after dilating the ureter the hemorrhage ceased.

Dr. BRANSFORD LEWIS of St. Louis stated that later studies indicated that focal infections from various parts of the body, in spite of there being an ascending infection from an infected bladder, gave rise to infection of the kidneys and hematuria. He recalled one case in which an infected tonsil was removed with benefit to the kidney condition.

Dr. JOHN T. MOORE of Houston, Texas, had had one case of cyst of the pancreas about the size of one's head, that did not give rise to hematuria.

Dr. RANDOLPH WINSLOW of Baltimore reported a case of exstrophy of the bladder operated on nearly thirty years ago, and gave the subsequent history of the case.

Giant Ureteral Calculus; Anomalous Development of the Genitourinary Tract.—Dr. IRVIN ABELL of Louisville reported the following cases: Case I, male, white, aged 32; date of first observation, August 17, 1915. Personal history negative for acute severe illness and venereal infection. Patient applied for relief of pain in his back of ten days' duration. Irregular left lumbar pain first noted at 18; at 28 there was a similar pain on the right side. Latterly pain recurred monthly but never sufficiently severe to require opiates, and until present attack persisting only a day or two. Heretofore, relief followed rest, hot baths, hot water bottle and coitus. Between paroxysms urinary frequency, four to five times daily; during an attack once to twice daily. Blood noted in the urine on a number of occasions. Present attack had continued without remission for ten days. Examination revealed patient thin, but well developed and muscular; pulse 100; temperature 100.2° F.; heart and lungs normal; right kidney palpable, tender, apparently large as medium-sized grapefruit. Left kidney not palpable; no tenderness on that side. Urine muddy-colored; acid, specific gravity 1020; marked trace of albumin, occasional blood and pus

cells, calcium oxylate crystals, amorphous phosphates and a moderate number of bacteria. Cystoscopy showed the bladder practically normal; left ureteral orifice appeared normal, catheter readily entered renal pelvis. Orifice of right ureter edematous, catheter encountering obstruction at 2½ cm. Urine from the left kidney showed no albumin or pus, an occasional blood cell. Blood count normal. Radiography disclosed a calculus in the pelvic portion of each ureter; left moderate size; right extended from the sacroiliac joint to meatus. A diagnosis was made of bilateral ureteral calculi, and right-sided hydronephrosis. Operation was performed August 19, 1914. A bilateral gridiron incision was made, enlarged downward by incising the rectal sheath; the peritoneum was displaced mesially, and the ureters approached extraperitoneally. There was considerable thickening about the right ureter; it was separated with difficulty from the surrounding structures. The ureter was excised at the pelvic brim; the calculus removed by traction. A similar procedure was done on the left side. Ureteral incisions were closed by interrupted catgut. The external wounds were drained by strips of rubber sheeting. The postoperative history was uneventful, the patient resuming work at the end of the third week. The right calculus oblong, with distinct curve at either extremity; length 7½ cm.; circumference 7 cm., weight 24 grams. The left zone was more ovoid, and weighed 2 grams. Case II. Female, white, aged 19. Date of first observation, September 3, 1915. Patient married three years, no pregnancy nor menstruation. No acute illness until the present. Ten days previously there was acute lower abdominal pain, nausea, vomiting, abdomen distended, tender; temperature 101° to 103.5° F.; pulse 110 to 120. Lesion was regarded as appendicitis by the attending physician. Symptoms subsided within a week. September 2, 1915, patient had a similar attack and was admitted to the hospital the following day; pulse 120; temperature 103° F.; abdomen markedly distended, exquisite tenderness of the lower zone. While her figure was typically feminine, examination revealed absence of vagina; external genitals normal in appearance. Urine acid, trace of albumin, slight sediment, few blood cells, many pus cells, and rod-shaped bacilli. Blood count; hemoglobin, 90 per cent.; white cells, 30,500, and polynuclears 82 per cent. There was a tender mass in the left pelvis. A median incision disclosed the pelvic kidney in front and to left sacroiliac synchondrosis. The right kidney, uterus, tubes, and ovaries absent. Operative finding; pyelitis in single pelvic kidney. Three weeks later urine from the ureter and bladder negative upon culture. Radiography disclosed renal pelvis normal in size and shape; a single ureter 3 or 4 inches long. Cystogram showed the bladder pressing upon kidney, the latter producing variation in normal vesical outline. The rectum in the right pelvis.

In Cases of Symptoms without Gallstones, What Disposition Shall Be Made of the Gall-Bladder?—Dr. LE GRAND GUERRY of Columbia, S. C., said his own personal results showed that in about 30 per cent. of the cases of gallstones without symptoms operated on, we failed to get permanent symptomatic relief. It is evident that 75 per cent. of the cases are cured by simple drainage of the gall-bladder, since the figures they had obtained showed that from 25 to 30 per cent. represented the cases that were not relieved. Manifestly it would be unwise and unnecessary to subject the 75 per cent. that could be cured by the simple method to the greater risk of a more serious operation. As we saw it, out of every 100 cases, 75 remained well after cholecystotomy, and 24 per cent. were not relieved permanently. In what cases shall the gall-bladder be removed? He did not feel that the advocates of cholecystectomy in those cases had completely made out their case. He was willing to grant that a certain percentage of those cases would be relieved by removal of the gall-bladder, the so-called strawberry gall-bladder, the cases in which there was an infection of the gall-bladder itself, but as we had already seen, probably a good many of those cases could be caused by conditions other than infection of the gall-bladder wall. Of the five cases he had operated on before the gall-bladder had been removed, the results had been as follows: in two cases the patients died on the third and fourth day after an effort on his part to establish communication between the common duct and the duodenum or stomach. The third case was alive two months after with a permanent biliary fistula. The other two cases were well, one two and the other three years after an anastomosis between the common duct and the duodenum. Accepting the

work of Archibald, it would seem reasonable that the division of the sphincter of the ampulla had a certain definite field of usefulness. Archibald had so treated his cases experimentally with good results. He believed that certain of those cases were best treated by the establishment of a permanent communication between the gall-bladder and duodenum. Lastly, his feeling was that that disease was like most other diseases, there were no hard and fast lines to be drawn, and that the best results would be obtained by a judicious selection of the operation to suit the individual case.

Cholecystostomy versus Cholecystectomy.—Dr. CHARLES H. MAYO of Rochester, Minn., stated that great progress had been made in surgery of the gall-bladder during the past twenty-five years. Diagnoses, instead of gallstones as in the past, were now as descriptive of the condition as cholecystitis, cholecystitis with stones, cholecystitis without stones (the inflammatory condition which produced them having subsided), or with duct and pancreatic complications. That there was still an opportunity for improvement in the treatment was shown by the fact that 370 patients with gall-bladder and gall-duct disease seen at their clinic during July, August, September, and October, 1915, 48 had been previously operated on, some of them twice, for the same disease. The mode of infection was still under discussion, the role of the portal circulation, permitting bacteria to make a frontal attack on the mucous membrane, if such vulnerability could be considered, was probably more common than ascending infection through the ducts. The experimental researches of Rosenow, however, had proved that the more common method of invasion was the rear attack at the base of the mucous epithelium of the gall-bladder, by bacteria conveyed through the general circulation. Cholecystostomy and the removal of stones cured symptoms of mechanical obstruction. Cholecystostomy did not cure chronic cholecystitis and could not restore the destroyed walls of the gall-bladder, or free the gall-bladder from adhesions. For these and for all cases in which infection was the major feature either with or without stones, cholecystectomy was the better method of treatment. In large groups of cases the mortality would be lower than that which followed cholecystostomy. Chronic pancreatitis with gastric symptoms might persist following cholecystectomy.

The Advantage of Separate Suture of the Mucous Membrane in Gastric Surgery.—Dr. RICHARD A. BARR of Nashville stated that the mucous and submucous coats of the stomach formed a very tough and substantial structure. It was very easy to divide the peritoneum and the muscle down to the submucosa and to separate them from it without cutting through. In the region of the pylorus a submuscular resection of the submucous and mucous coats might be made with less technical difficulty than was encountered in doing a pylorotomy, and in many cases served much the same purpose. In pylorotomy and partial gastrectomy division down to the submucosa and suture of this structure and the mucosa before dividing them prevented soiling, gave very satisfactory control of hemorrhage, and the completed suture line was much less rigid and less thick than that gotten by the usual method. The dissection of a flap of overlying peritoneum and muscle from ulcers lying on the anterior wall, with cauterization of the ulcer, suture of the submucosa with infolding, and replacement of the flap was already an established procedure.

Caudal Anesthesia in Genitourinary Surgery.—Drs. BRANSFORD LEWIS and LEO BARTELS of St. Louis stated that this was the method of anesthesia proposed and first used by Lăwan and was based on the use of saline injections into the sacral canal suggested in 1901. It was the nerve-blocking method of local anesthesia applied in the sacral canal, using a combination of novocaine, potassium sulphate, and adrenalin as the local sedative fluid. At the time of the making up of the report they had used the method in eighty-five cases, and with such success that they felt justified in making a report. This method was to be distinguished from that of spinal anesthesia in that the solution was not injected into the spinal canal. The spinal canal was separated from the sacral canal by the cuff of dura mater which closed down on the cauda at about the first segment of the sacrum. An injection of fluid, therefore, into the sacral canal, did not reach up into the spinal canal. The object of the injection served to obtund the sensibilities or anesthetize the nerves issuing from the anterior sacral foramina that form the sacral plexus. One of the most important nerves of

this plexus was the pudic distributed to the bladder and prostate and other genitourinary organs. By anesthetizing this nerve, an anesthetic condition of the organs mentioned was secured. Directions for preparing the solution were given, and their experience with dosage was detailed. It was found preferable to use larger quantities of weaker solution, rather than small quantities of stronger solution to obtain the anesthetic effect. It was found that the pressure effect of the anesthetizing fluid was strongly influential in securing success. From 50 to 90 c.c. of the fluid was now being used. The particular value of the method lay in the very debilitated, decrepit and aged patients that required major work in genitourinary surgery. Prostatectomies done suprapubically, the removal of vesical stones, and cystoscopies in hypersensitive individuals, had all been done with marked success and comfort under this method of anesthesia.

Some Observations on Local Anesthesia.—Dr. HERBERT P. COLE of Mobile, Ala., presented a résumé of his major operations performed within his clinic during the past two years. This group included 185 abdominal operations upon the appendix, gall-bladder, intestines, ovaries, and uterus. He reported one case of nephrectomy, three radical cases of amputation of the breast for carcinoma, two cases of decompression of the skull, and one exenteration of the orbit for sarcoma. Seven abdominal operations were performed during pregnancy without maternal mortality. Seven major operations were performed upon children under two years of age, with one death from bronchopneumonia twelve days after establishing a Littre artificial anus in a child three days of age. Forty-seven cases were operated upon between the ages of fifty and eight-seven; with a mortality of 4.5 per cent.—two deaths, the deaths occurring in one case on the eighth day following enterostomy, and the fifth day of ileus and peritonitis in a patient sixty-five years of age. The second death occurred on the fourth day following drainage, and the sixth day in peritonitis in a patient sixty-eight years of age. He concluded that the selection of local anesthesia as the anesthetic of choice in the cases offering grave mortality risks was a factor of safety too potent to be neglected.

Hyatid Cysts of the Liver with Report of Two Cases. Dr. GEORGE BEN JOHNSTON of Richmond, Va., had had two cases of hyatid cysts of the liver during the past two years, and about six months ago another case was reported in a Richmond Hospital. This was remarkable because of the fact that prior to 1913 only two cases of tenia echinococcus infection were reported from Virginia, and 250 from the United States and Canada. The Virginia cases occurred in Alexandria and Staunton. There was, however, another case that was infected in Virginia, but was reported from Buffalo by Cary and Lyons. Their two cases came from the rural districts and they were frequently exposed to infection both from dogs and from meat which was not properly inspected. The case that was operated on in Richmond several months ago occurred in a foreigner who had lived in this country only a short time. Their cases, however, were not from the region in which the epidemics in hogs had been reported. They had in mind those infected regions and were waiting to see if there would be a relative increase in infections of the tenia echinococcus type amongst their patients living in those localities. Surgery was the only method of treatment for this condition. Wherever possible, it was always best to remove the cyst *in toto*; if that was impossible, to remove as much of the cyst as possible and drain, and if this was impossible to aspirate the cyst.

Intussusception in Infants.—Dr. LEWIS S. McMURTRY of Louisville said that intussusception was essentially an accident in infancy, since three-fourths of the cases obtained in children under two years of age. In a series of 300 cases collected by Grisel, 204, that is 68 per cent., occurred in breast-fed infants under one year of age. Of all the varieties of intestinal invagination the ileocecal was by far the most common, and almost invariably was found in cases of infants and young children. Grisel concluded that in infancy 82 per cent. at least were of this variety. In dealing with a case of suspected intussusception in a baby, the physician should, if possible, decide the diagnosis before leaving the house. He should study the case closely, give it immediate attention, and weigh each symptom carefully. The fate of the patient depended upon early diagnosis. When abdominal section was done success would depend more upon the operator's expedition and skill, with refinement of manipulation, than perhaps

in any other abdominal operation. The young infant was easily shocked. It was very important that the invagination should be reduced by pressure from the apex of the intussusception, so that it was pushed out from within instead of being pulled out. The appendix should not be removed unless absolutely necessary, and every effort made to abbreviate the operative procedure. In his own experience he had found chloroform preferable for anesthesia. It was well known that after release of the invaginated intestine there was a tendency for recurrence of the invagination. To prevent this several operative procedures had been utilized. One was to shorten the mesentery by securing it in a position parallel to the intestine. Eliot adopted the method of attaching the disinvaginated intestine to the parietal peritoneum by a few sutures of catgut. This latter method proved satisfactory in his cases. Every addition to the operation that was not absolutely necessary should be omitted, and every moment of time should be conserved in the patient's interest. Even with the best judgment and skill, the mortality of the operation during the first twenty-four hours stood at 40 per cent. When an irreducible invagination was found, the best procedure perhaps was to establish an artificial opening in the intestine and wait until a later date for the resection of the invaginated bowel. There was, however, but little choice between this and resection of the intestine at the time, since both procedures were followed by an extremely high mortality. He reported four illustrative cases of intussusception in infants under one year of age. Two late cases were not operated upon and both died. One was recognized early, operation done and recovery insured; another came late, and unless there was an error of diagnosis, patient recovered without operation.

The Operative Treatment of Pyloric Obstruction in Infants with a Review of Sixty-six Personal Cases.—Dr. WILLIAM A. DOWNES of New York City stated that this report included sixty-six cases operated upon in five and one-half years. All presented the characteristic symptoms. A tumor was palpated in every case before operation, and this finding was verified at the time of operation. This experience threw new light upon the etiology or pathology of the condition. The theory best explaining the symptom-complex was, that a true malformation was present at birth consisting of an abnormal thickening of the circular muscle of the pylorus, and to this was added an edematous condition some ten days, or later, after birth. The edema probably resulted from the increased activity of the stomach necessary to force an increasing amount of food through the narrowed and elongated pyloric lumen. Gastroenterostomy was performed upon 31 of the 66 cases, the remaining 35 being operated according to the method of Rammstedt. This latter method consisted of making a longitudinal incision 2 to 3 cm. in length, which was carried through the serosa and hypertrophied circular muscle fibers down to the mucous membrane. This incision was well liberated. Of the 31 cases in which gastroenterostomy was done there were 11 deaths—a mortality of 35 per cent. of the 20 discharged as cured, 2 afterwards died of gastroenteritis and 1 died of diphtheria. The remaining 17 were well and had developed normally. Röntgen ray examination showed the stomata working satisfactorily, and little or no bismuth passing through the pylorus. Of the cases dying in the hospital—a number began to vomit late in their convalescence, reoperation and autopsy offered no satisfactory explanation for the return of symptoms. After this unsatisfactory experience it was decided to give the partial pyloroplasty of Rammstedt a thorough trial. Consequently, this operation had been done in the last 35 cases. In this series there were 8 deaths—a mortality of 23 per cent. Of the 27 discharged as cured, 2 had died since leaving the hospital, the remaining 25 were well extending over a period from a few weeks to one and one-half years. In no case had there been a return of the symptoms. The general condition of the babies submitted to the two types of operation averaged the same. A number in each series were almost moribund at the time of operation, and this accounted for the immediate mortality. The cases operated according to the Rammstedt method vomited less and were easier to feed after operation. The advantages of the partial pyloroplasty over gastroenterostomy were time consumed for operation, the former requiring less than half that necessary to perform the latter, the operation required much less surgical skill than gastroenterostomy, and the continuity of the gastrointestinal tract was preserved. Röntgen ray ex-

amination one and one-half years after operation and autopsy on case dying three months after operation demonstrated the fact that the stomach functioned normally, and that the tumor entirely disappeared after this procedure.

Colon Resection and Its Indications.—Dr. FRANK MARTIN of Baltimore submitted the following summary: (1) Cancer of the colon was an undisputed surgical problem, and it should be dealt with by widespread resection, the sooner the better. (2) In analyzing the results of colon resection for other than malignant causes the most careful and critical judgment should be exercised and no case reported favorably unless the case had been under the strictest surveillance for a considerable period. (3) The operation was distinctly of the major type and should be undertaken only in obstinate and exaggerated cases. (4) It was distinctly too hazardous to be undertaken purely for the relief of constipation alone. (5) There were dangers attending it and they should not be lost sight of. (6) Theoretically, the colon was a part of the human anatomy which could be dispensed with without inflicting serious damage. In most cases a considerable portion of the colon was left, the sigmoid, and in a good many cases a part of the descending colon, which was sufficient to compensate for and take on the function of the portion that had been removed. (7) Thirst was not complained of in any of his cases in spite of the physiologists pointing out this as one of the theoretical dangers. (8) The chief dangers that we had to keep before us were the operation *per se*, and the immediate and postoperative obstructions that were liable to follow.

The Use of Iodine in Combating the Peritonitides.—Dr. J. A. CRISLER of Memphis said that his large experience in the use of this drug and the clinical manifestations after its use in these cases, led him to firmly and conscientiously believe that the infected fluids that were free in the cavity were at once sterilized, and that the absorption of toxins, which after all, was the *sine qua non* mortuary factor of peritonitis, was immediately terminated for at least twenty-four hours. Also an outpouring of serum and of new phagocytes was immediately encouraged. He was strengthened in this belief by the fact that a high temperature in these cases almost invariably fell in a few hours down to normal or nearly so. Furthermore, there was an abundant serous drainage following, which was in excess of usual drainage common in other methods. This tended to disgorge and in a measure wash out the subserous cellular tissues, which might receive some beneficent antiseptic effect through a process of osmosis directly from the iodine that had come in contact with the inflamed serosa. In his investigations of the elimination of the iodine element, it had never appeared in the urine earlier than the eighteenth hour after its use in the abdomen, and then only in very small quantities. The height of elimination was attained about the seventy-second hour. He conjectured from this study that the absorption of toxins was held in abeyance for a like period. All the facts brought out by these studies, including clinical, physiological, and chemical, combined to show the truth of this assertion. During this period there was developed in the patient an autoresistance and toleration, quite sufficient to overcome the disease. From December 1, 1914, to December 1, 1915, he operated in 673 abdominal cases with 23 deaths. In this number of operations he had 104 pus cases. In other words, slightly over 15 per cent. of all of his abdominal cases were due to pus in the abdomen, either localized and walled off, or free with no effort at walling off. In this latter series he had one death, this patient reaching him in a moribund condition and utterly hopeless.

Typhoid Perforation; Peritonitis.—Dr. FRANK D. SMYTHE of Memphis stated that the positive indications for operation in connection with typhoid fever were: (1) Typhoid after the first week, usually the third, with sudden pain in the abdomen, severe, persistent, growing progressively worse, and muscle spasms. (2) Pain, at first local, rapidly extending, with or without nausea and vomiting. (3) Tenderness upon pressure, local and general. After reporting a case of typhoid perforation with unusual and interesting history, he stated the points of special interest were: 1. Diagnosis of peritonitis. 2. The man felt sufficiently well to engage in a wrestling match as a matter of choice when the perforation occurred. 3. He had not lost a day from his work nor missed a meal. 4. The only evidence of trouble prior to perforation was an estimated loss of about 10 pounds in weight and a feeling of malaise

two weeks preceding the operation. 5. That immediately operation was urged by his family physician. 6. The diagnosis of peritonitis was made from the pain in the abdomen, its severity and persistence plus rigidity. 7. Tenderness upon pressure. 8. Collapse. 9. Vomiting early with intermittent nausea. 10. Widal made daily for seven days and proved negative. On the third day after operation blood culture was made with negative result, and on the eighth day a positive Widal was obtained.

Plastic Operations for Acquired Deformities of the Face.—Dr. J. SHELTON HORSLEY of Richmond, Va., called attention to the fact that plastic operations on the face were usually not life-saving procedures, and relieved not only the discomfort and mental anguish of the patient, but also the patient's associates who must daily view the deformity. Plastic surgery of the face required a kind of ingenuity to meet unusual conditions and to make things fit. The age and health of the patient must be given due weight. While general principles could guide in certain groups of cases, each case was a law unto itself. Therefore, a paper on such a subject must deal largely with reports and illustrations of individual cases. Dividing the face regionally, he reported three cases of deformity of the forehead following the loss of a portion of the anterior wall of the frontal sinus. The infundibulum was probed, and if not sufficiently large, gauze was run through it. Then small skin flaps were taken from the margins of the defects and turned in, cutting the pericranium farther out than the skin so it could be overlapped like a double-breasted coat. The raw surface was covered by sliding flaps from other portions of the forehead. A deformity of the eye caused by fracture and displacement of the portion of the bone to which the inner canthus was attached was corrected by replacing the bone and shortening the upper lid. Deformities of the nose were corrected by grafting bone from the rib or by sliding a flap including mucous membrane and cartilage from the septum of the nose. Large openings in the cheek were closed by transplanting a flap from the forehead with the attached anterior temporal artery dissected out and transplanted in the new position. Defects in the lip were corrected by various methods. When the whole thickness of the lip was involved, as after noma, flaps which included mucous membrane were slid up from the cheek. In other instances flaps were transplants from the neck or from the arm. When the arm was used the pedicle was cut in about two weeks.

Salpingitis Secondary to Appendicitis.—Dr. JAMES E. MOORE of Minneapolis said that a number of years ago the writer's attention was first called to the possibility of appendicitis being the cause of salpingitis by the following case: A single woman, aged thirty, was brought from one of the smaller cities of Minnesota to Minneapolis for operation with a diagnosis of salpingitis. She was taken to a gynecologist who firmly believed that the only cause of salpingitis was infection from the gonococcus, and in the absence of any evidence of infection in the vagina and the presence of an imperforate hymen concluded that it was impossible for the patient to have salpingitis, and discredited the attending physician's diagnosis. The patient was then brought to the author, who found that the patient gave a history of repeated attacks of inflammation in the lower abdomen and pelvis, and by rectal examination a solid mass could be made out in the pelvis. The vagina was healthy and hymen intact. There was no history of disease or unnatural discharges from the vagina at any time. The diagnosis of salpingitis was confirmed, although the possible cause was not understood. Operation was performed, evidence of repeated attacks of appendicitis were found, with the appendix closely adherent to the right ovary and tube, and both tubes distended with pus. The appendix and tubes were removed, and the patient fully restored to health. It was evident that the infection had not extended to the uterus, because it was left and had never caused symptoms. This led the writer to conclude that this was a case of salpingitis secondary to appendicitis. This occurred many years ago at a time when facilities for careful bacteriological examinations were not at hand, so that there was no means of knowing what bacteria were present. Since that time the writer had observed a number of cases that had confirmed his conviction that some cases of salpingitis were due to an infection from the peritoneal side caused by an appendicitis, but only two more cases were cited to emphasize the point the author was trying to make. The author believed that these cases demonstrated that infection of the Fallopian tube

might occur from the peritoneal end, and that when it did it was usually due to appendicitis. He believed that it should be accepted as an established fact that a certain small percentage of cases of salpingitis were due to appendicitis, so that when looking for possible causes of a pelvic inflammation we might take this fact into consideration.

Pseudomucinous Cysts of the Appendix and Ruptured Pseudomucinous Ovarian Cysts.—Dr. FRED WARREN BAILEY of St. Louis reported two cases of pseudomucinous cysts of the appendix, one case complicated by ruptured pseudomucinous ovarian cyst. The uncomplicated case was present in a young man, aged twenty-five, who had undergone a drainage operation for acute suppurative appendicitis thirteen months previously. There had been at intervals a mucopurulent discharge from the sinus which persisted since the first operation. The patient had suffered several attacks simulating acute appendicitis and lost weight rapidly. Patient had temperature of 100° and local signs of acute appendicitis. Operation revealed clubbed appendix with constriction 1 inch from its tip. A smooth-walled spherical tumor, which proved to be a pseudomucinous cyst, had pushed its way through the wall of the appendix. Between this tumor and the tip, the lumen was patent for the distance of 1 cm. Between the tumor and the cecum, the lumen was patent and undergoing an acute inflammatory process, accounting for the acute symptoms. The appendix and distal loop of ileum were surrounded by omental sac and bathed in pseudomucinous exudate. The appendix was removed, the pocket sponged and treated with 3 per cent. iodine. The sinus was dissected and the wound closed without drainage. Recovery was uneventful. Case 2 was one of ovarian cyst, capacity four liters, which had evidently ruptured several weeks prior to operation, with no definite symptoms except general abdominal tenderness and rapid loss of weight. About two liters of pseudomucinous material was removed from the abdominal cavity, large masses having adhered to abdominal viscera. The appendix was 7 cm. long and 2.5 cm. in diameter. The wall was translucent, smooth, tense, and fluctuant. There was a small opening near the tip from which gelatinous material exuded. The contents of the ovarian tumor and appendix proved to be pseudomucin. The diseased structures were removed, the abdomen thoroughly irrigated with saline, and closed without drainage. Patient had right side inguinal hernia which was repaired under local anesthesia on the tenth day. She was discharged from the hospital thirty days from date of entry, and had improved in health steadily since. There was no record of malignancy following ruptured pseudomucinous cysts of the appendix, but the danger was far greater in those of ovarian origin. No diagnosis of the condition was made previous to operation. He believed protection against such tumors lay in early exploration of all surgical abdominal lesions.

Genital Elephantiasis Following Extirpation of Inguinal Glands.—Dr. J. T. WINDELL of Louisville reported two cases, as follows: Case 1.—Mr. N., aged 37, single, date of first observation June 25, 1911. The patient then presented an enormous elephantiasic enlargement of the scrotum and penis which he said began early in 1910. The scrotum measured 16 inches in circumference; the penis was 11 inches in length, and at its largest part 12 inches in circumference. The patient contracted syphilis in 1903, and according to his statement, he had been under antisyphilitic treatment continually since then. Two surgical operations had been performed for the removal of enlarged and infiltrated inguinal glands, one in 1905, and the other in 1909, but for what character of pathology the patient did not know. Dense fibrous tissue scars, adherent to the underlying structures, were present in both inguinal regions. The scar tissue was more abundant in the left groin, which probably explained the greater scrotal enlargement on the corresponding side. Local treatment consisted of an appropriate suspensory apparatus and antiseptic dressings. At no time was there any acute inflammation of the penile tissues; but the scrotum, owing to the continuous exudation of lymph from its surface, at times became infected and exhibited evidence of acute inflammation, which was relieved by suitable antiseptic applications. On July 10, 1911, the Wassermann reaction was three plus. The patient was treated for several months by mercury in its various preparations and modes of administration, and later by salvarsan. November 11, 1913, Wassermann reaction two plus. Twelve days after the administration of

salvarsan, December 7, 1913, there occurred considerable swelling, pain, and redness of the left arm around the elbow joint, sufficiently severe to cause the patient to remain in bed and require the constant attention of a trained nurse. Such manifestations following the injection of salvarsan must be exceptional, and were difficult to explain excepting upon the hypothesis that there existed a local lymphatic or vascular abnormality preventing prompt elimination of the drug. The symptoms subsided within six weeks, and there was no similar recurrence following subsequent salvarsan injections. Salvarsan was again administered on March 29, April 14, and May 10, 1914. September 2, 1914, Wassermann reaction one plus. There had been no reduction in the genital hypertrophy; the supportive bandage had been continued. The patient was in excellent physical health. He had consulted several eminent authorities, all of whom had agreed that surgery was not indicated. Case 2.—Mr. B., aged thirty, single. On September 10, 1912, three months after bilateral inguinal adenectomy for enlarged and suppurating glands, probably of tubercular origin, the patient presented an immense hypertrophy of the penis. It was unaccompanied by redness or pain, and the scrotal tissues were apparently uninvolved. Several deep scars were present in each groin from the previous operations. Having in mind the unfortunate cases just reported, it was thought that this was another of a similar character, and the diagnosis was made accordingly. An appropriate suspensory apparatus was applied, and the patient was requested to report three days later for further observation and treatment. However, he failed to return, and from information subsequently received, it appeared that the penile hypertrophy subsided within two or three months.

Ulcer of the Jejunum with Report of a Case.—Dr. ROBERT C. BRYAN of Richmond, Va., said that his experience in surgery of the stomach and with one case of ulcer of the jejunum hardly justified the presentation of a symposium of classical features which might be dignified with the title "Diagnosis of Ulcer of the Jejunum." Keen stated that if more attention were to be given to oral sepsis and to the gastric condition of hyperchlorhydria relapse of ulcer might be prevented. Apparently ulcer of the jejunum was found associated with other pathological states of the upper alimentary tract. Since so little was known and understood about primary ulcer of the jejunum, it might be said that these associated conditions should be more readily translated and diagnosed by the routine laboratory procedures, and when so worked out and accounted for, the remaining untoward expressions might be laid at the door of a suspected ulcer of the jejunum. Gastroenterostomy being one of the causes of jejunal ulcerations, one should hesitate to perform the operation for primary ulcer of the jejunum. In appropriate cases excision, resection, or enterectomy were apparently the operations of choice.

The Estimation of Resistance Prior to Surgical Operations.—Dr. A. C. SCOTT of Temple, Tex., stated that many puzzling situations could be cleared up and an occasional disaster averted were we to systematically enter into our records something which tended to group and emphasize the various elements of lowered resistance and pit the net resistance remaining against the factors involved in each operation to be overcome, being mindful of the fact that in every surgical operation two forces were pitted against each other, one tending to destroy life, and the other engaged solely in an effort to save it. For the purpose of illustration, he would select three factors which might enter into an operation, any one of which might be severe enough to result fatally in a person possessing normal resistance. He referred to hemorrhage, trauma, and inhalation anesthesia, each of which had been measured experimentally. Other factors more difficult to measure were fear, pain, and muscular effort. The physiological effect of each of these factors was modified by the time consumed. On the side of resistance we had an unlimited number of factors concerned in lowering the standards. They seldom appeared singly and often many of them would be combined in a single individual. They might be roughly classified as follows: Constitutional weakness from inheritance and environment; previous debilitating diseases of any character; recent trauma by either injury or operation; starvation, drug habit, and psychic depression. The maximum or ideal resistance was illustrated in a fully developed adult whose breeding, habits, and environment had been conducive to the acquisition of a complete, well-balanced and functional-

ly perfect organism. The ill effects of the anesthetic were rapidly multiplied as the patient's resistance was lowered from various causes. This applied to all the operation factors. As the resistance was progressively lowered each factor of the operation which tended toward fatality was increased in varying proportions as the fatal percentage was approached. Perhaps the most uniformly marked deleterious effect of each operation factor was to be observed in those cases whose resistance was decidedly lowered from some form of toxemia. In no department of medicine was the teamwork of an efficient staff of examiners and laboratory workers of more value than in the work of estimating a patient's resistance prior to contemplated surgical procedures. The importance of systematic examination for the purpose of noting the various things which might lower resistance was parallel to that made for diagnostic purposes.

Sarcomata in Unusual Situations.—Dr. HUBERT A. ROYSTER of Raleigh, N. C., stated that among his records he had found six cases in which sarcomata were discovered in unusual locations, either growing from tissue rarely the seat of such growths or exhibiting other characteristics out of the ordinary. The first one was fibrosarcoma of the sheaths of the musculospiral and median nerves. The second, rhabdomyosarcoma of the trapezius muscle. Three, fibrosarcoma of the breast. Four, single-celled sarcoma of the abdominal wall. Five, lymphangiosarcoma of the coccygeal region. Sixth, myosarcoma of the buttocks.

The Treatment of Lymphosarcoma with Radium.—Drs. HOWARD A. KELLY and CURTIS F. BURNAM of Baltimore pointed out the differences between lymphosarcoma and Hodgkin's disease, and the various leucemias, and excluded those latter conditions for consideration in the near future. They drew attention briefly to the life history of lymphosarcoma, beginning as a local infection and growing more or less rapidly, metastasizing, and finally invading the lymphatic system, more or less, of the whole body, and invariably causing death in a period of from several months to a couple of years. Surgery had always stood impotent in the presence of lymphosarcoma, even in such an accessible region as the neck, and when located in the breast or abdomen it was, of course, even beyond the dream of surgical relief. It was Nicholas Senn, who, in 1903, opened up the great question of the ray therapy of these affections. The authors presented a series of twenty cases, all but two identified by a microscopic examination of the tissues, and all the cases submitted to Dr. Kelly's clinic for treatment by surgeons from various parts of the country. Most of the patients were in an extremely advanced stage of the disease and twelve of them had been operated upon, and those with one exception were sent as a last desperate hope with rapidly recurring masses in the neck. Out of that group of twenty, thirteen, or 65 per cent. were apparently cured. Six cases had died of the disease, five of that group had been operated upon, and all were advanced bad cases but one. On the basis of this experience they believed that lymphosarcoma ought not in the future be operated upon, but should be subjected to radium therapy at the earliest possible moment. The results were found to improve if the cases were obtained early, and they confidently expected to increase their percentage of recovery from 65 up to 90 per cent. or over. The amounts of radium used varied from 441 to 2,000 mgs. distributed over different areas for several hours and repeated at intervals of weeks or months. While in the early cases the diseased area alone was treated, in the later cases the entire lymphatic system of the neck, axillæ, and torso have been included. There were several instances of primary extensive lymphosarcoma of the mediastinum. Those also responded just as readily as those more superficially placed. In view of those results and the rescue by radium of this most distressing malady from the realm of the incurable, all future cases should be given the benefit of a thoroughgoing radium treatment at the earliest possible moment.

Subcutaneous Dermic Fistula in the Treatment of Ascites.—Dr. WALTER C. G. KIRCHNER of St. Louis related his experience with the Oberst operation, employing certain modifications of technique. In principle, the operation consisted in the employment of a pedunculated portion of the skin from the abdomen, which was buried subcutaneously in such a manner that a flap projected into the abdominal cavity. Thus no substance foreign to the body was used in providing continuous drainage.

Conservative Pelvic Surgery.—Dr. FLOYD W. MCRAE of Atlanta said he had done conservative operations on 338 women. Of this number he had been able to get reports to date from only ninety-three—thirty-two of whom had reported pregnancies. Practically all had gone to full term and been delivered of healthy children. One woman had had three children, another two; another had had three or more induced abortions. Another was delivered of a living child by cesarean section on account of uremic convulsions. Both mother and child were not in good health. He had written the 198 cases that he had not kept in touch with, and hoped to receive definite information from many of them to incorporate in his paper before publication. Of the 338 women, seventeen had had subsequent operations done by him or other surgeons. He had only included in this record the women whose pelvic organs were left in a state compatible with possible future pregnancies. It did not include individuals whose tubes or uteri were removed, or where partial hysterectomies were performed precluding pregnancy. In his work he had resected cystic ovaries, preserving all healthy stroma, suturing accurately with fine catgut. He had endeavored to so separate adhesions, embedded ovaries and tubes as to leave the least possible area of raw surface; hanging up prolapsed ovaries, plicating the ligaments, so readjusting uterus, tubes, and ovaries as to approach as nearly as possible the normal arrangement. A very large majority of those women had been relieved of their suffering and restored to all the privileges and enjoyments of healthful womanhood.

Gangrenous Abscess of the Lung.—Dr. D. F. TALLEY of Birmingham, Ala., reported a case of gangrenous abscess of the lung in a young married woman after the birth of her first child. It was now more than 10 months since the operation was performed and patient was in perfect health. All cases of abscess and gangrene of the lung should be opened and drained unless the abscesses were multiple and inaccessible. Tuffer cured two cases by lung compression, by tacking in fat and omentum intrapleurally over the diseased area, but this method seems inadequate for most cases as there is need for actual drainage, and there might be a sequestrum of necrotic lung that must come away before the abscess can close.

Fracture of the Femur.—Dr. ALEXIUS MCGLENNAN of Baltimore reported fifty-five cases of fracture of the neck of the femur that had come under his personal observation in the past eight years. Of that number thirty-six recent fractures and seven old fractures were treated, and twelve patients were not treated. In all cases full abduction, with downward traction and inward rotation, was the position obtained in the reduction of the fracture. The full abduction was assured by fixation of the pelvis by abducting the sound leg, and the inward rotation by lifting the trochanter forward. Impaction was separated in six cases, and in the seventh was not disturbed because the impaction occurred with abduction of the thigh. This was a unique observation. Various forms of fixation were used from firm plaster of Paris cast to loose tying up of the thighs. Direct extension by ice tongs was used in three handicapped patients, one of whom died. Nailing the fracture was done twice. For the old cases, bone graft was used once, nailing twice, removal of head once, subtrochanteric osteotomy twice, freshening fragments once. Of the recent cases, four died, and in one the fracture failed to unite. One of the old cases resulted fatally, and one patient still walks on crutches seven years after treatment. Treatment was refused by two young adults, with vicious union. Ten patients were not treated on account of feebleness, circulatory, pulmonary, renal, or nervous symptoms. Two were living several years after the injury, aged 88 and 90 years respectively. Delirium tremens and evidence of drug addiction, or uremic manifestations, make the prognosis grave. Loss of control of bladder or rectum seems to indicate an inability to stand fixation. The effect of the healed fracture on earning capacity was noted in ten cases, the average loss being 15 per cent. after a period of disability lasting from six months to one year and three months, with an average close to one year. The occupation of those patients included hotel manager, restaurateur, farmer, housekeeper, seamstress, laborer, tailor, motorman, and market driver.

Treatment of Fractures.—Dr. W. P. CARR of Washington, D. C., related his experience and results in 7,000 cases treated in the Emergency Hospital and compared his results obtained by conservative methods, which experience had proven safe and efficient, with those of

other surgeons using other methods. He concluded that fractures were not generally treated as well as they were twenty years ago for the following reasons: There was generally (1) too ready resort to amputation; (2) too ready resort to open operation; (3) too great liability to choose a faulty method of operating. He believed this condition of affairs had been brought about by a too great dependence upon the x-ray before reduction and fixation and too little use of it afterward and a consequent neglect of surgical anatomy and muscular action in various fractures. He strongly condemned operation of any kind when not really necessary and believed it to be necessary in comparatively few fractures. When operation became necessary he advocated the use of one or two wire loops to prevent shortening and condemned any method looking to rigid fixation in alignment. He presented numerous skiagrams to show bad results following the use of Lane plates and thought they had come into use because surgeons did not understand the simple mechanical principles involved in the use of wire nor the physiological principles of bone growth and regeneration. He thought there was a generation of younger surgeons coming in who, under the teaching of Mr. Lane and others high in authority, or through a misapprehension of their teaching, had made it their practice to operate upon nearly every fracture coming into their hands, and that it was our duty to teach them that this was not necessary except in unusual cases, to urge a greater study of surgical anatomy and of non-operative methods which in nearly all cases should be tried for a week or so before operating. If, at the end of a week, it was found by measurement, palpation and x-ray examination, that they could not maintain good position of the fragments, it was still time enough to operate, and to better advantage than at first. The patient lost no time for preparation of the tissues for union had been going on during this week and they were also in better condition to resist infection. The only indications for the operation were for reduction in those cases where it could not otherwise be done and to prevent shortening or to prevent muscular action from tilting or pulling some short fragment into bad position. Operation of any kind should never contemplate the prevention of angular deformity or rotation which could be perfectly controlled in other ways, preferably by casts. He emphasized the importance of getting extension and counter-extension in applying casts in non-operative cases and in such a way as to prevent rotation.

Cysts of the Appendix.—Dr. JOHN T. MOORE of Houston, Tex., stated that during the present year he operated upon a patient with a cyst of the appendix of the pseudomyxomatous type. He had previously operated upon two others which he reported in detail, and through the courtesy of Dr. Hamilton, he was able to report a fourth case operated upon by him. This year he had had a cyst case of the type mentioned by Matas. One would be inclined to think that cysts of the appendix ought to be of very frequent occurrence, but if one was to judge from his own experience and that of the reported cases, the condition was not very common. According to Castle, in an analysis of 13,158 post-mortem examinations, twenty-nine cases of cystic appendix were found. Two conditions seemed to be necessary to cyst formation: (1) A partial or complete blocking of the lumen. (2) The contents must be sterile or almost sterile. The lumen might be only partly blocked to allow a sufficient pressure to destroy the lining epithelium. But with a communication with the intestines the material was apt to become infected, and thus lead to the formation of a pus appendix, with necrosis of its walls. Such cases were too acute to allow cyst formation. The process must be a slower one. The epithelium must be only slowly impaired so that the cells were allowed to functionate somewhat.

Granulosis Rubra Nasi.—A. Winkelried Williams reports the case of a girl, aged 13, who had suffered from the condition since early childhood. Her nose was red and the skin wet with sweat. There were hyperidrosis and lumpy swellings (sweat-gland abscesses) in the armpits. The hands and feet were cold and moist. The localized hyperidrosis of the cartilaginous part of the nose was very marked until about two months ago. A few deep-seated papules, under the diascop, gave the appearance of something between a hidrocystoma and lupus. The patient was now much better, in fact, she was getting toward the age when recovery usually takes place.—*Proceedings of the Royal Society of Medicine.*

Miscellany.

The Stereopticon Loan Library of the U. S. Public Health Service.—The stereopticon loan library established by the United States Public Health Service consists of over 2,000 views, the majority of which are original, dealing with the aspects of various public health problems. Additions are constantly being made to the collection. The slides are classified by diseases or subjects, the following being the respective divisions of the library: Alaska, Children and Children's Diseases, Health Exhibits, Hookworm, Indians, Leprosy, Living Conditions, Malaria (including the malarial mosquito), Milk, Miscellaneous Subjects (sewage disposal, fumigation and cleaning of railway cars, and views relating to Rocky Mountain spotted fever), Mouth Hygiene, Parasites and Organisms, Pellagra, Plague, Rural Schools, the activities of the U. S. Public Health Service, Smallpox, Trachoma, Tropical Diseases, Tuberculosis, typhoid fever, yellow fever. The slides are loaned to physicians, health organizations, educators, welfare workers, and others, without cost. Persons desiring slides should advise the bureau as to what subjects they are interested in so that the proper catalogues may be forwarded. The slides should be selected by number, and the request made upon the application blank. If desired, the Public Health Service will undertake to make the selection, provided the applicant will state what he wishes to illustrate. There is no arbitrary limit within which the slides are to be returned, but as the demand far exceeds the supply, it is expected that they will be returned at the earliest possible moment. It is expected that slides broken by careless handling or packing will be replaced; these to be ordered from the government contractor by the U. S. Public Health Service and the bill therefor to be paid by the borrower. It is requested that in returning the slides a letter of transmittal be forwarded, stating the approximate number of persons to whom the views have been shown. Photographs, from which it is possible to obtain slides of public health interest, will be gladly received and promptly returned.

New and Appetizing Foods.—German ingenuity is again evidenced in a despatch to the *New York Sun*, which quotes the *Berliner Tageblatt* as describing a valuable new food produced by the director of the municipal slaughter house at Graz. He has succeeded in extracting the albumin from ox blood in such a manner that the odor and taste of the blood are entirely removed. The result is a yellowish powder which has been tested under the name "haematalb" in the hospital at Graz and elsewhere, and is said to have proved to be an excellent substitute for chicken.

Inaugural Dissertations of the University of Kiel.—The *Münchener medizinische Wochenschrift* for November 23 gives a list of forty-one inaugural dissertations of Kiel University for six months of the past year. It may be a coincidence or due to war conditions that no less than twenty-eight of these articles, or 70 per cent., are devoted to neurologic and psychiatric subjects. The organic and functional neuropathies are about equally represented. Several papers each are devoted to intracranial tumors, hysteria, choreatic psychoses, paresis, alcoholism, and melancholia and scattered ones on traumatic neuroses, paranoid, familial psychosis, encephalitis (following measles), abscess of the brain, multiple sclerosis, stigmata of degeneration, and epilepsy.

ROCKY MOUNTAIN SPOTTED (TICK) FEVER.

REPORT OF AN INVESTIGATION IN THE BITTER ROOT VALLEY OF MONTANA.

By HENRY C. MICHIE, JR., B.S., M.D.,
CAPTAIN, MEDICAL CORPS, U. S. ARMY,

AND

HOUSTON H. PARSONS, M.D.,
GLENDALE, MONT.

ASSISTANT SURGEON, NORTHERN PACIFIC RAILROAD.

IN presenting this paper we wish to make a résumé of Rocky Mountain spotted (tick) fever, using all available data, and to incorporate the essential results of eighteen months' research on this disease, as it occurs in the Bitter Root Valley, Montana. The laboratory work was carried on in the laboratory at Fort Missoula. Patients were seen and studied through the courtesy of local physicians in Missoula, Victor, Stevensville, and Hamilton, and one patient admitted to the Post Hospital at Fort Missoula. This investigation covered a period from July, 1911, to January, 1913, but was unavoidably interrupted at that time by extensive army maneuvers. The delay in summarizing the work was due to the probability of continuing the investigation and completing many unfinished experiments.

In all, five strains of virus were studied; No. 1, obtained through the courtesy of the U. S. Public Health Service, Washington, D. C.; Nos. 2, 3, 4 were transferred to guinea pigs from patients; No. 5 was obtained from Dr. McClintic, U. S. P. H. S., working at Victor, Montana. In comparing these various strains the following conclusion was drawn: No. 1 was carried through three generations and discontinued as unsatisfactory. Nos. 2, 3, and 4 were intraperitoneal transfers of two cubic centimeters of blood into guinea pigs from human cases, during the first week of the disease. These strains were carried on separately from pig to pig. In no case was the strain interrupted by a mixed infection. The virulence was comparatively low at first, increasing with passage; gangrene was absent at the first transfers, but usual after about the fifth transfer. The incubation period grew shorter, smaller amounts of virus were used in continuing the strain (this being essential to prevent the early death of the animal), and the animal generally showed a more severe type of infection with increased passage. The University of Chicago has carried a strain in pigs for more than two years, but we do not know their results. Most of the work in Fort Missoula was carried on with strains Nos. 2, 3, and 4. Strain No. 5 was the most virulent, it was isolated from the wood-tick, found infected in nature by Dr. McClintic. It had been passed through one or two pigs before we received it.

Whether this happened to be an unusually virulent strain, or whether the direct transfer into pigs from the tick produced the more severe type of infection, we are not in position to say.

On account of lack of space clinical charts of patients and of guinea pigs will be generally omitted, only a summary being given with as correct an interpretation as possible. Reference to the disease as it occurs in other States was obtained from former articles and by letters received directly from the secretary of the State Board of Health of the various States. Other references to cultures and staining will not be made on account of their negative character, but, briefly stated, every culture medium of which we have been able to find an account was made and tried. These included the spirochæta medium (Noguchi), hemoglobin, placenta juice, egg, exudate (hydrocele and pleuritic fluids), and Bass's plasmodium medium. Many were tried anaerobically and aerobically, and at temperatures from that of the ice-box to 45° C. Some in continuous light (electric), others in absolute darkness. These cultures were checked by microscopic and macroscopic examinations. Animal inoculations were made when deemed advisable. Of the stains and staining methods, every stain and method, both common and rare, that we had access to, was tried. Many extemporized stains were prepared and used; smears of blood, aqueous humor, synovial fluid, smears of bone marrow, liver, spleen, kidney, adrenal gland, brain, lung, muscle, testicle, ovary, epididymis were made, stained, and examined. Sections of organs were made and stained by Levaditi's method. Besides the ordinary methods, staining was done by electricity (electrolytic); staining was also done under great pressure, using a specially constructed apparatus with several different stains. Various fixing methods were used, also fresh specimens were examined. Daylight, electric, and dark field illumination, also variously colored diaphragms were used with the microscope. Many interesting artefacts were observed and proven to be such by control methods. We can give the *Piroplasma hominis* theory of Anderson no support. The finding of trypanosomes in the blood of normal gophers, as stated by Stiles, was confirmed by Prof. M. J. Elrod, of the University of Montana. We are inclined to think that further examination of concentrated blood specimens and the transfer of infected blood into species markedly different from the original (donor) will reveal interesting results.

From the standpoint of spotted fever the Bitter Root Valley of Montana is of prime importance, and it may be advisable to describe it briefly. The valley is L shaped; commencing at Darby, it runs due north for fifty miles to Missoula, where it makes a right angled turn to the west for twenty-five miles, ending at Frenchtown. The boundaries

are ranges of the Rocky Mountain Chain. Those on the west and south, the Bitter Root Mountains, are very high and rugged, reaching an altitude of 10,000 feet (Mt. Lo Lo), capped with perpetual snow. The foot-hills rise more suddenly on the west and south; there is also more timber in these regions, and wild animals and ticks are more abundant. On the east and north, the slope of the foot-hills is gradual; there is more cultivation, fewer ticks, and the mountains are of a lower altitude, probably none over 6,000 feet. The valley proper is bisected from beginning to end by the Bitter Root River, running due north and then west. This river is crossed in numerous places by bridges and fords, and is probably not more than 150 feet wide at the broadest place. The valley is thickly settled for this section of the country; there are small towns every five or ten miles along the river and railroad. The soil is wonderfully fertile, and was formerly the bottom of a huge lake. This latter is shown by a characteristic subsoil of about forty feet in places. Beach marks are prominent on the surrounding mountains, and the rocks are invariably smooth and round as seen in the river bed. There are many small, clear, and swift streams crossing the valley and feeding the river. Vegetation is abundant, with a great variety of wild flowers, a beautiful display of colors following each other in sequence. Commencing about April the fields are yellow with dandelion, turning later to purple with wild hyacinth. By June the landscape has again changed its hue, this time to pink, due to the blossoms of the "bitter root." The Flat Head tribe of Indians, who formerly settled the Bitter Root Valley, named the river, plant, and valley. This tribe has for years used the roots of this plant for medicinal and economic purposes. Annually they migrate into the valley from the reservation to collect these herbs. After gathering the specimens they grind them to a pulp by means of an improvised stone mortar and pestle, roll this pulp into balls, and store it for future use. The Indians use this in the form of a porridge or tea for all ailments. Dr. Parsons, on investigating the plant chemically and physiologically, finds that it contains a bitter principle of no therapeutic action other than that of a bitter tonic. The plant disappears after a few weeks, the fields in turn becoming green, and then brown as the dry season approaches with the increasing temperature.

Mosquitos are numerous during the warm months, bedbugs and the body louse are not uncommon in places where they are usually found. The human flea (*Pulex irritans*) is comparatively scarce, but fleas are found in abundance on wild animals. The surface and underlying soil are not teeming with insects as seen in the Southern States, and in places long under cultivation.

The following mammals are found in the valley and neighboring mountains: Badger, black and brown bear, yellow-bellied and white bellied chipmunk, coyote, domestic cow and cat, dog, black-tail and white-tail deer, elk, domestic goat, mountain goat, horse, mountain lion, white-footed, meadow, and domestic mouse, martin, mink, porcupine, domestic and wood rat, rock-cony, cotton-tail, and snowshoe rabbit, domestic and mountain sheep, swine, rock, pine, and columbian ground squirrel, woodchuck, weasel, and wolf.

Synonyms.—Rocky Mountain Spotted (Tick) Fever, Black Fever, Spotted Fever of Montana, Blue Disease, Rocky Mountain Fever, Spotted Fever

of Idaho, Piroplasmosis hominis, Tick Fever of the Rocky Mountains, and Black Measles.

Definition.—An acute febrile disease of unknown cause, occurring endemically during the warm months in the Bitter Root Valley of Montana, Snake River Valley of Idaho, and in other Rocky Mountain States; is characterized clinically by a sudden onset with a chill and continuous fever, enlarged spleen, early albuminuria, slow pulse, pain in the head, neck, back, and joints, especially wrists and ankles, and a characteristic eruption spreading over most of the body including the palms and soles. Pathologically it is characterized as a hemorrhagic septicemia, and is transmitted by the tick, *Dermacentor venustus*.

History.—Nothing is known of the early history of Rocky Mountain spotted fever in the Rocky Mountain States. The first published account is contained in the Annual Report of the Surgeon General of the Army, 1896, when Captain M. W. Wood, Medical Corps (now Lieut. Colonel, retired) gave an account of this disease as occurring near Boise Barracks, Idaho; this information was transmitted to the Surgeon General on the regular monthly sanitary report. According to early settlers, it appears that spotted fever has been known in the Snake River Valley of Idaho as far back as 1873, and in the Bitter Root Valley of Montana since 1890. These dates by no means represent the first appearance of the disease in these places. The Bitter Root Valley was settled by the Nez Percé and Flat Head tribes of Indians, who remained there until about 1890. It is a fact that in an Indian settlement, history dates back no further than the memory of man. It was after the transfer of these Indians to the Flathead Indian Reservation, some forty miles distant, and after the valley became settled by the white man, that tick fever became of great importance. It seems probable, however, that spotted fever existed among the Indians while they resided in the Bitter Root Valley. An old Indian chief of these tribes, who lived many years in the valley, tells us that at certain times of the year (spring) the Bitter Root Valley was visited by evil spirits, and that it was particularly hazardous to visit certain canyons at this time, as for instance Lo Lo canyon. It is now well known that tick fever appears very soon after the advent of the first warm days of spring. We also know that there are localities in the valley which are heavily infected, for example west of Florence. The connection between facts known at the present day and the statements made by the old Indian Chief would indicate that the disease existed in the Bitter Root Valley at least seventy-five years ago. However, there is no authentic report of a case so far back, and there are no records of cases having existed among the Indians. After this territory was evacuated by the Indians and taken up by the white man, about 1890, we get a history of "black measles" occurring every spring and summer, affecting a few persons, nearly all of whom died. This too must have been tick fever.

As spring approaches, the snow on the foothills and in the valley begins to melt, causing the streams to become swollen, and low lands marshy. These warm days do more: ticks that have remained quiescent during the colder months, now appear by the millions. They can be found in all stages of development, larvæ, nymphs, and adults. They may be found on all animals roaming the fields, both wild and domestic; they are also found on plants,

especially hay. It speaks for the keen insight of some of the early settlers, either in Montana or in Idaho, who, associating the appearance of ticks with the appearance of tick fever, so named the disease; and to differentiate it from African tick fever affecting man, and Texas cattle (tick) fever affecting cattle, as well as because of its peculiar distribution and the mottled skin eruption produced by it, it was named "Rocky Mountain spotted (tick) fever." The first detailed description of the disease was written by Dr. E. E. Maxey in 1899, on "The So-called Spotted Fever of Idaho."²⁵ His description was very accurate, and the definition formed by him stands to-day. In 1902, Dr. R. Gwinn published an account of spotted fever, as occurring in the Klondike, Alaska.¹⁷ Dr. McCullough, of Missoula, Montana, read a paper on the disease before the Montana Medical Association.²⁷ During the summer of the same year, Wilson and Chowning of the University of Minnesota visited the Bitter Root Valley to study tick fever. As a result of their investigation they attributed the cause of the disease to a "babesia"; believing this hematozoon to be parasitic on the squirrel (*Spermophilus columbianus*) and to be accidentally transmitted to man by the wood tick (*Dermacentor venustus*). They offered no experimental evidence to support their statement. However, squirrels and ticks are numerous in the valley during the spotted fever season.

In 1903, Anderson of the United States Public Health Service investigated the disease, supported the tick transmission theory, and described a Piroplasma, the *Piroplasma hominis*.³ Stiles, in 1905, from his zoological investigation, discredited the tick transmission and the *Piroplasma hominis* theories. At that time he described a trypanosome as occurring in the blood in normal gophers.³⁵ The trypanosome theory was supported by Ashburn of the Army.⁴ Ashburn and Craig of the Army Medical Corps, in 1908, published an excellent paper on this disease and tsutsugamushi, pointing out their differences.⁶ In this paper they accepted the tick transmission theory of spotted fever. In 1906, King found proof of tick transmission, and from 1906 to 1910 the late H. T. Ricketts of the University of Chicago, through untiring efforts and through most scientifically conducted investigations, completed a monumental piece of work, and laid the foundation for all subsequent campaigns on this disease.³¹ He proved the tick transmission, the similarity of Montana and Idaho strains, found naturally infected ticks on animals, and proved that these ticks remained infectious through their entire life cycle; he disproved the trypanosome, piroplasma, water, and miasm theories of the disease.²¹ He demonstrated the immunity conferred by one attack and the susceptibility of the rhesus monkey and guinea-pig. He produced an immune serum and demonstrated its limited value, demonstrated the effect of inoculation with virulent blood on the gopher and rabbit, opened the first scientifically planned investigation of spotted fever, and laid out plans for tick eradication, which plans were left unfinished by his sad death from typhus fever, in 1910, at Mexico City.³¹ The credit for having transmitted the disease from man to man by the tick is due to McCalla and Brereton, at Boise, Idaho.²⁶ McClintic of the U. S. P. H. S., in 1911, commenced his investigation of spotted fever, locating his field laboratory at Victor, Montana, the most densely infected area of the Bitter Root Valley. He found

infected ticks in nature, and carried the disease along in many guinea pigs. His efforts were largely directed toward tick eradication and search for a chronic source of the infection in some lower animal of the valley. He constructed large vats and dipped domestic animals in an arsenical preparation to destroy the ticks that were liable to be dropper around the buildings.^{28, 29} He recommended burning the fields and clearing away underbrush in order to destroy many ticks. He also trapped and killed thousands of small wild animals. There were fewer cases in the valley that year, eight in number, with seven deaths, including the able investigator himself, who was presumably bitten in his laboratory by an experimentally infected tick. Frick of the U. S. P. H. S. took up the work where his colleague McClintic left off, and has found that ninety per cent. of ticks that get on sheep, die, presumably due to the lanoline. He is now interested in grazing sheep over the valley in a well planned manner as a means of tick eradication.¹⁵

Other persons who have furnished valuable information on spotted fever are Anderson, R.,³ Banks, N.,⁷ Bishopp, F. C.,⁸ Cooley, R. A.,^{11, 12} Davis, B. F.,¹³ Hineman and Moore,¹⁸ Henshaw, H. W.,¹⁹ Hunter, W. D.,²⁰ King, W. W.,²¹ Maver, M. B.,^{23, 24} Pearce, R. A.,³⁰ Spencer, W. O.,³² Wood, M. W.,⁴⁴ Kieffer, C. F.⁴³

Geographical Distribution.—Spotted fever is remarkably endemic and spreads slowly. The first detailed account of this disease was given by Dr. E. E. Maxey of Boise, Idaho, in 1899, and since that time it has been reported in the Klondike, Alaska, and in many places among the Rocky Mountain States. According to the information furnished by the secretaries of the health boards of the States west of the Missouri River, it is believed that the following statistical table is as accurate as can be made at the present time. To the best of our knowledge experimental work has been done on Idaho and Montana strains only, and although we do not question the accuracy of reports of the disease in other places, we do know that a correct diagnosis is sometimes impossible without laboratory facilities. The vast majority of the work was done on the strain found in the Bitter Root Valley. In 1908, Maxey, then secretary of the State Board of Health of Idaho, collected data on three hundred and eighty cases occurring in that State during the year. This was done through letters of inquiry to every physician practising in the State.²⁵ Spotted fever is not known to exist in other parts of the world, and although one of its names is quite similar to African tick fever, there is no similarity between the two diseases.

The following table shows the distribution of Rocky Mountain Spotted Fever in the States west of the Missouri and Mississippi Rivers:

Washington:	Grant and Lincoln Counties.
Oregon:	Southeastern portion of the State (Crook, Grant, Malheur and Harney Counties).
California:	Lassen County.
Idaho:	(See map).
Nevada:	Humboldt and Washoe Counties.
Montana:	Missoula, Ravalli, Granite, Powell, Park and Carbon Counties.
Wyoming:	Generally distributed over the State.
Utah:	Box Elder County.
Arizona:	(Not reported.)
Colorado:	Garfield County.
New Mexico:	Absent.
North Dakota:	Absent.

South Dakota: Absent.

Nebraska: Absent.

Kansas: Absent.

Oklahoma: Absent.

Texas: Absent.

British Columbia: Absent.

Montana reported 12 cases during 1914, 9 cases in 1913, 8 cases in 1912, with 7 deaths in 1912.

Idaho reported 386 cases in 1914, with 15 deaths, by months, as follows: March, 21 cases, with 1 death; April, 97 cases, with 2 deaths; May, 154 cases, with 6 deaths; June, 86 cases, with 4 deaths; July, 25 cases, with 2 deaths; August, 3 cases, with no death.

Nevada reported 12 cases during 1911 and 1912, with no death, and 9 cases during 1913 and 1914, with no death.

Dr. Ralph Falk, Secretary, State Board of Health, Idaho, has admirably tabulated the cases occurring in that State during 1914, 386 in number, with 15 deaths. The geographical and numerical distribution is shown in the accompanying map of Idaho.

Just why there are so many more cases in Idaho than in Montana is not known, and why the mortality is about 3 per cent. in the former, and 75 per cent. or more in the latter is still unsolved. Neither is it known in which State the disease first appeared. Reference to the geological map will show the two infected areas communicating through Lo Lo Canyon, a pass in the Bitter Root Mountains. It is in this canyon that the most virulent type of the disease occurs, and it is probable that here lies the connecting link between the two States.

Zoological Distribution.—Spotted fever has not been found to exist in nature in any lower animal, in either the acute or the chronic form. All late in-

vestigators have worked along this line, believing it to be the keynote to the situation. It is possible to infect a few of the lower animals by inoculating them with virulent blood. Among these the rhesus monkey and the guinea pig reproduced the disease quite similarly to that found in man. White and black rabbits are partially immune, the gopher, a semi-cold blooded animal inhabiting the valley in large numbers, may be infected and later the strain recovered, but as this animal does not run a constant temperature in health (it varies from 98° to 102° F.) and does not manifest the disease acutely, it is a very unsatisfactory animal for experimental work. White mice, domestic cats, and dogs are reported immune.²⁹ The horse possesses a certain amount of immunity, but has been used to produce an immunizing serum. The following small animals of the Bitter Root Valley have been found susceptible to transfers of virulent blood: Ground squirrel (*Tamias striatus*); rock squirrel (*Spermophilus cinerascens*); woodchuck (*Arctomys monax*); yellow-bellied chipmunk (*Tamias luteiventris*); and the wood rat (*Neotoma cinerea*). The ground squirrel, rock squirrel, woodchuck and chipmunk were found susceptible to a single bite of an infected wood tick.^{28, 29}

Etiology.—The specific cause of spotted fever has not been determined. Since the mode of transmission is through an arthropod, a biological carrier, and on account of certain similarities to other protozoan diseases, it is very probable that the cause when isolated will be found to be a protozoan. A great deal may be said of the predisposing causes, but briefly, man does not possess natural immunity to spotted fever, and any condition that makes him liable to be bitten by an infected tick is a predisposing cause to this disease. The only means of transmission now known is by the bite of a tick. Experimentally lower animals are inoculated with the hypodermic syringe subcutaneously

Map of Idaho, showing the number and distribution of cases of Rocky Mountain (tick) fever during 1914, 386 cases with 15 deaths.

Distribution in the United States of the Rocky Mountain spotted-fever tick, *Dermacentor venustus*. The large dots show localities where the species has been collected. The small dots indicate the probable range of the tick. (Original.) U. S. Bureau of Entomology.

or intraperitoneally, and in nature man is inoculated subcutaneously by the bite of an infected tick. These ticks live entirely on blood, and although they are only occasional feeders, they must feed before each molt. During the act of feeding the hypostellum is plunged into the skin and an irritating fluid ejected from the salivary glands. This fluid causes a local hyperemia, and retards blood clotting; the tick now feeds. Since the infection is in the salivary gland of the tick, as proved by Ricketts,²¹ it is plainly manifest how man is infected.

The ticks (*Dermacentor venustus* and *D. modestus*) are very generally distributed throughout the Rocky Mountain States, as shown by the map. These are the species that Ricketts and McClintic found infected in nature, and the species with which the transmission was proved.

Although there are other species in the infested zones, and there is limited experimental evidence that ticks from several Eastern and Southern States may transmit the infection, this contention has not been proved.²⁴

The life cycle of the tick is in four stages: egg, larva, nymph, and adult. The time required to complete this cycle varies from a few months, under the most favorable circumstances of feeding and thermal conditions, to two years, as determined by Mr. M. V. King of the United States Bureau of Entomology, working near Florence, Montana. Males and females, feeding on warm blooded animals, mate and copulate, and fertilization takes place. After engorging with blood, which usually requires several days, the female drops from its host and remains quiescent for about two weeks, when ovipositing commences. A cream colored mass of several thousand eggs is laid, and the female dies. After about a month, at summer temperature as that in Montana, the eggs hatch, small "seed ticks" or larvæ appear. They are light yellow in color, have three pairs of legs, no sexual apparatus or spiracles. The larvæ are about the size of a common pin's head; they gradually become darker in color, and attach themselves to some animal, usually a small one. They feed for about a week, then drop off to molt, which takes about a month. Nymphs emerge from this molt with four pairs of legs and spiracles, but no genital apparatus; these nymphs are about 2 x 4 millimeters in size, but the species cannot be determined at this stage. Like the seed ticks, the nymphs seek a host, and becoming attached, feed for about a week and drop off. After remaining active for several weeks, a white shell forms over the nymph, and it then enters upon the second molting period, which under the most favorable conditions is completed in about a month. When the tick emerges, it is a fully developed adult, ready to recommence the cycle. We have kept nymphs and adults in the laboratory over a year without feeding, but larvæ must be fed or they die. Molting occurs only subsequent to feeding. By laboratory experiments Moore²⁵ has shown that the minimum time required for the tick to infect a guinea-pig was one hour and forty-five minutes, the average time being ten hours; that it requires about twenty-four hours for the normal tick to become infected from a pig suffering from the disease. This has its practical bearing on the possibility of finding the insect before it becomes attached and infects the individual. Ricketts has proved that both males and females can transmit the infection, that the infected fe-

male transmits it to about 50 per cent. of her progeny, and that eggs, larvæ, nymphs, and adults of an infected female contain the virus.²¹

It is not definitely known in what stage the tick hibernates, but very probably as a nymph. As the first few warm days of spring appear, the small animals, especially ground squirrels and gophers, put in their appearance. Shortly afterward ticks become very plentiful. King has shown that the ground squirrel emerges from its hole free of ticks, but soon becomes infested by them. From about April to July each year ticks are abundant; very few can be found after August, although we have found some in October. This period corresponds to the tick fever season. The first case in 1912 was reported on April 31, and the last on August 25. There was another case reported to us from Hamilton on September 26, but this patient died the following day, and the diagnosis was not confirmed by the guinea-pig test. This last case was exceptionally late in the season. Although ticks of various species are found the world over, it will be noticed that the spotted fever fields are from about 40° to 47° north latitude, and from about 2500 to 4000 feet above sea level. Another characteristic of the disease is that it is confined to definite areas, a perfect endemic disease. For example, spotted fever appears every year on the west side of the Bitter Root River, and very rarely is there a case on the east side, and when such occurs the history of a visit to the west side can usually be obtained. There are fewer ticks on the east side and Frick explains this by the greater number of sheep grazing there.²⁶ There is free communication between the two sides of the river by means of bridges and fords; men, animals, and materials cross freely. Not only is the disease confined to the west side, but almost to certain places, like west of Hamilton, Victor, Florence, Stevensville, and in Lo Lo canyon. And it is to be kept in mind that this is a disease of the country; all cases developing in a city are in persons who have recently been to the country.

Race, age, sex, habits, and occupation play no part in the acquisition or transmission of the disease other than the liability to being bitten by an infected tick. We are unable to find any evidence of spotted fever affecting a negro, but this may be due to the scarcity of the race in infected districts. Heredity apparently plays no part in the spread of the disease, and there is no such thing as chronic spotted fever in man. One attack establishes a well defined and prolonged immunity in man as well as in the rhesus monkey, guinea-pig, gopher, and rabbit. There is no available record of a second attack in man; repeated attempts to infect guinea-pigs, once they have recovered, have failed. Ricketts showed that the young of immune female guinea-pigs possessed a certain amount of immunity, and that this was not due to the milk ingested by nursing.²¹ We too have found it unreliable to use the offspring of immune pigs as they strongly resist infection and the resulting experiments are untrustworthy. Therefore, it is quite probable that children of a mother rendered immune by an attack of spotted fever possess a certain amount of immunity.

Symptoms.—Premonitory. After an incubation period of three to eight days the disease is suddenly ushered in with a chill or a feeling of chilliness, pain in the head, neck, back, and joints, especially in the wrists and ankles, with malaise, anor-

exia, increased rapidity of pulse and respirations, constipation, irritation, and inflammation at the site of the tick bite. Persons are frequently bitten in heavily infected districts, and it is to be remembered that one cannot differentiate the bites of infected from non-infected ticks by the appearance of the lesion.

Initial Symptoms.—The pains continue, and the large joints which exhibit no swelling or redness, become exquisitely painful on the slightest movement. About the fourth day, counting from the first day of the fever, a deep-seated macular eruption appears on the wrists and ankles, which spreads to the palms, soles, forearms, and calves. The eruption becomes darker and spreads to the dependent portions of the body. Often it is petechial and becomes confluent, forming spots of a dusky hue, about an inch in diameter. This latter feature is more commonly seen on the back and appears late in the disease. The eruption is not elevated, does not itch, and does not disappear on pressure. The pulse is slow compared with the temperature; there is an initial rise in the pulse rate; a pulse of one hundred or more is a bad sign in the later stages of the disease. It is full and of good tension, but becomes dicrotic toward a fatal termination. The temperature rises suddenly to about 102° F., and continues to rise daily with but slight remissions in the morning, until about the seventh or eighth day, when it reaches about 105° or 106°. In favorable cases there is a fall about the ninth or tenth day, ending by lysis in a very slow convalescence. Patients show signs of toxemia very early in the disease, as evident by the headache and arthritic pains, as well as by stupor and apathy, which usually give way to muttering delirium, carphologia, and subsultus tendinum by the fifth or seventh day. Slight catarrhal pharyngitis and conjunctivitis, as well as nausea, are common at the beginning. Vomiting is usually a late sign and appears when the disease has assumed a hemorrhagic nature. We have seen "black vomit" (partially digested blood) on the ninth day, but it may occur earlier. The tongue presents the same appearance as seen in severe febrile diseases. Constipation is present as a rule and continues well into convalescence. The circulation is sluggish, with engorgement on the venous side. This produces a peculiar cyanotic appearance of the face, especially about the mouth, is quite characteristic, and occurs early in the disease. Nephritis appears early; albuminuria with a reduction in the amount of the urine occurs almost from the start. In severe cases great numbers of granular, and sometimes blood casts, are found in the urine. These continue through the severe febrile period; suppression of urine, and retention or incontinence are of frequent occurrence. The spleen is palpable early, is greatly enlarged and hard—not the enlarged soft spleen seen in typhoid fever. In unfavorable cases the skin becomes hyperesthetic, there is incontinence of urine and feces, temperature remains high, brain symptoms increase, icterus appears, first seen in the conjunctiva and then becoming general; the eruption is more profuse and confluent, with a purplish hue, pulse exceeding 110 (in the adult), and death follows within twenty-four hours.

In cases that recover, the temperature falls by lysis between the ninth and fourteenth day; morning remissions and evening rises are often experienced as late as the sixth week of convalescence.

The urine increases in amount, the eruption fades with a fine desquamation, the mental condition improves, and pains disappear. Convalescence is very slow and the mental condition of patients recovering from spotted fever remains sluggish for a long time after the disease has subsided. The macular eruption can be brought out by hot baths, even months after the temperature has returned to normal. A late symptom is gangrene of the prepuce, scrotum, and testicle, sometimes of the faucial pillars. In such cases the testicle first becomes quite painful, then adherent to the scrotum. This complication is said to be more common in Idaho than in Montana, on account of the longer duration of the disease in the former State. It is common in guinea-pigs, and like the incubation period, varies with the virulence of the virus.

The blood is a valuable guide to the diagnosis; it becomes darker in color from the start, due to destructive processes and poor aëration; the coagulation time is also increased. There is an initial increase in the number of leucocytes, this number later falling below ten thousand, where it remains in favorable cases. A sudden increase in the leucocytes late in the disease is a very serious sign. We have found a count as low as one thousand the day prior to death, and a rise to 28,000 three hours before death in the same case. Another feature is the increase in the large mononuclear and transitional cells. Myelocytes are often present, and occasionally one finds a nucleated red cell. In severe cases there are leucocytes that do not resemble any in the usual classification, these and have been accounted for by us as "unclassified." In the seven cases of human blood examined during 1912, the "Arneth Index" was a reliable guide to the patient's condition.

Arneth Count.

*Present.
**Leucocytes were extremely scarce on May 19, 1912, and the above count is based on forty cells after one hour's search.

The count on May 20, 1912, was made three hours before death.

Eosinophiles were reduced in number or entirely absent in all cases examined during the attack; an increase of eosinophiles is a favorable sign. The red count is not affected; hemoglobin usually 100 per cent., and sometimes darker than the hundred mark on the Talquist scale. It is very difficult to determine the coagulation time accurately, but after working with normal blood, and using the same apparatus under conditions as similar as possible, we found the coagulation time of diseased blood to be invariably increased to sometimes twice the normal time, which we estimated to be four minutes.

The virus is contained in the blood from the appearance of fever until the temperature reaches normal; after that time we have been unable to transmit the disease. In order to keep a strain going in guinea-pigs, the transfer should be made at the height of the fever. Transfers should be made before death, or mixed infection is very apt to occur. According to Ricketts, and confirmed by us, the virus is present in the red cells, white cells, and serum. The serum was obtained free of cells by an electric centrifuge, at 3,500 revolutions per minute, examined, and injected into pigs. Red cells were separated in a sodium citrate solution by the centrifuge method, removed by the means of a pipette from the bottom of the tube, washed eight times in normal salt solution, examined, and injected. White corpuscles were more difficult to obtain in a free state. This was done by injecting aleuronat into the pleural cavity of an infected rabbit. In twenty-four hours the irritation had caused an accumulation of leucocytes that were most carefully removed through the chest wall without contamination or without being mixed with blood from the incision. These cells were washed several times, examined to see that they were free of red cells, and a normal guinea-pig was inoculated with them. These tests were made with controls in each case, and checked by immunity tests and postmortem findings. Lymph also contains the virus²¹.

The liver and spleen were also shown to be infectious after having been macerated and washed several times, the mass taken up in salt solution as an emulsion, and injected. Spleen, liver, and blood of a guinea-pig suffering from spotted fever were fed separately to normal pigs, without the latter showing any evidence of infection. These same animals were not immune, as shown by subsequent inoculation. It, therefore, does not seem possible that man can be infected by the mouth, and for this reason we decided that examination of the stools was not indicated. Animals manifest the disease in from two to five days when inoculated intraperitoneally, and in five to ten days when inoculated subcutaneously; man is infected subcutaneously by the tick. The incubation period also varies with the virulence of the virus, and the degree of virulence also shows variations. The virus is far more virulent in Montana than in Idaho, and in our experience increases with passage through pigs to about the tenth transfer. By this time the incubation period has become shorter, the disease more severe, and death occurs earlier. Such animals almost invariably manifested gangrene of the scrotum. After the tenth transfer the disease seemed to become milder. Dr. McClintic furnished us with a strain obtained from a naturally infected tick. This was the most virulent of the five strains used

in the experiments; we found it necessary to use small amounts of blood in making transfers (about 2 minims) in order to prevent the early death of the animal. The virus is not destroyed by storage in the ice-box for a week, and requires 55° C. for twenty minutes in order to destroy it (Ricketts). It will not pass through a No. "N" Berkefeld filter in twelve hours. Virulent blood serum was diluted with salt solution, and pigs inoculated with the filtrate. Where the animal manifested the disease prior to filtration, the results were negative after filtration. There is no difficulty in transmitting the disease from man to guinea-pigs during the height of the disease. We accomplished this many times, using both whole and defibrinated blood. The disease as it occurs elsewhere than in Montana, is of considerable less virulence. The eruption and toxemia are less marked, the disease is less acute, more prolonged, mortality lower, gangrene and other complications more common in Idaho than in Montana.

Pathology.—Gross Pathology. The following data are based on the observation of seven human cases, with complete postmortem findings in three, and on numerous complete autopsies on guinea-pigs. We disagree with the authorities on the subject of "early and complete rigor mortis." It has been our experience that rigor mortis comes on slowly, that the animal heat leaves the body slowly, and that decomposition sets in early. Local embalmers support us in this statement; some of them claim to have had cases where marked decomposition had set in before the corpse was cold or rigid. The most conspicuous features in viewing a body dead of spotted fever are the general saffron color of the body and conjunctiva, due to the intense jaundice, very little emaciation, lividity of the area around the mouth, small petechial and macular spots over the body, more marked on the arms and legs, and prominent bluish confluent blotches on the dependent portions of the body. The face remains free of eruption, and macules only are seen on the palms and soles. On incising the skin, the dark color and fluidity of the blood is very noticeable. We have not noticed any enlargement of the superficial lymph nodes in man, although it is quite common in guinea-pigs. The site of tick bite can usually be found in the form of a papule, surrounded by an hyperemic zone. The cerebrospinal nervous system has not shown sufficient and constant lesions to account for the marked brain symptoms. Organs of special sense have shown nothing abnormal. This has also been the case with the lungs and pleurae, except for occasional complications, pneumonia being not an uncommon sequela. The right heart and large veins are engorged, left heart comparatively empty. The heart muscle is darker in color and softer than normal, occasionally showing hemorrhages under the visceral pericardium. Diaphragm negative, stomach, intestines, and omentum show no constant change except jaundice; occasionally small hemorrhages are seen in the intestinal walls. Spleen, liver, and kidneys are the organs mostly affected. The spleen is always enlarged, often twice or more the normal size, is dark in color, firm, and friable, bleeds freely on section, and its tissue is disorganized. The liver is also darker than normal, bleeds freely on section, is uniformly enlarged, and bile stained; gall-bladder shows nothing abnormal. The kidneys, too, are acutely enlarged, and hemorrhagic throughout the entire organ. All of these organs show subcapsular hemorrhages. Adrenals

are enlarged and hemorrhagic. Bladder and prostate negative. Gangrene of the scrotum and prepuce was seen in three of the cases treated by us; testicles adherent and hyperemic, tunica vaginalis showing acute inflammation, epididymis soft and jelly-like. Gangrene of the pudenda and ears was often seen in pigs, but not after the first transfer of human blood. Testicles of guinea-pigs are not constantly seen in the scrotum, they are at times in the abdominal cavity, but the changes are more common when the organs are down. Both the ovaries and testicles are hyperemic in pigs. All our human cases were men, so there was no opportunity to observe human ovaries. The pancreas shares in the acute congestion. Bone marrow is darker in color than normal and somewhat fluid in consistency.

Microscopic Pathology.—We have done no microtome work on this disease other than the preparation of tissue by the Lavaditi method of examining for spirochetes. Quoting Le Count of the University of Chicago,² "The changes are of two sorts, those connected with the occlusion of vessels and the more diffuse lesions affecting the entire group of organs. The diffuse changes are hyperplasia of lymphoid tissue, and cloudy swelling and acute fatty changes in organs commonly the seat of such lesions in acute infectious diseases; the focal lesions are more varied in their nature since they include not only the process leading up to the inclusion of vessels, but the results of such obstruction, necrosis in different degrees, and the hemorrhages responsible for so many of the clinical and gross anatomic features of the disease, as well as for the name 'spotted fever.' In sections of skin, liver, spleen, kidney, and adrenal, both vascular occlusion and the necrosis resulting from obstruction were present." In guinea-pigs the disease seems quite similar to that in man. Skin manifestations are not the same, but an eruption is sometimes noticed on white pigs. The question naturally arises, if tick fever were to occur in full blooded negroes, could it be diagnosed?

Diagnosis.—A sudden onset with chill and fever, pain in the neck, back, ankles, and wrists, without redness or swelling, and the history of tick bite in a spotted fever section will immediately cause one to suspect the presence of this disease. The fever is continuous and higher each day; by the fourth day an eruption appears on the ankles, wrists, soles, and palms, with a slightly cyanotic appearance about the mouth. Repeated chills throughout the disease are common. There is early albuminuria, the spleen enlarges rapidly, and occasionally there is abdominal tenderness. The initial leucocytosis, with increase in the large mononuclears and reduction in eosinophiles, along with the absence of malarial plasmodia will differentiate the disease from malaria. The eruption, sudden onset, arthritis, and negative Widal reaction, will rule out typhoid fever. The most difficult disease to differentiate tick fever from is typhus fever. The eruptions are quite similar, but as a rule appearing first on the ankles and wrists in spotted fever, and on the abdomen and chest in typhus. The meninges are constantly involved in typhus, but give negative findings in spotted fever. The temperature rises more suddenly in typhus and ends in a crisis between the tenth and fourteenth day of the disease, usually preceded by a pseudo-crisis, and ends by lysis in spotted fever. The pulse is rapid in the former and slow in the latter. Guinea-pigs are very suscepti-

ble to spotted fever, while quite resistant to typhus. Typhus is transmitted by the body louse, spotted fever by the tick. The similarity of clinical symptoms is quite evident in the two diseases, suggesting a close relationship; however, that the two are not one and the same disease is shown by cross immunity tests.³¹

Treatment.—There is no specific treatment for spotted fever, and as in diseases caused by protozoa, immune sera are a failure both as a prophylactic and in the actual treatment. Ricketts produced an immune serum, using the horse, and this work was later carried on by his co-workers at the University of Chicago. It was used on guinea-pigs and on human cases without encouraging results, and is of no practical value.

The patient should be put to bed and a brisk purge should be given, a bowel movement being secured daily by purgatives or enemata. Sponge bath for temperature over 102.5° F.; although the temperature frequently does not respond to hydrotherapy, and the hypersensitiveness of the patient causes him much discomfort during the bath, he invariably feels better after the sponge. The diet is to be exclusively liquid, so as to increase the fluid intake and to tax the system as little as possible. On account of the early, persistent, and serious nephritis and profound toxemia, as much water should be taken as possible, at least one quart a day, and preferably in the form of lemonade. Salines by rectum are beneficial. Quinine, coal tar products, arsenic, atoxyl, continuous warm boric acid baths, and many other drugs have been tried and discarded as worthless. Sodium cacodylate, first used on spotted fever patients by Dr. Kellogg of Stevensville, Montana, and reported on favorably, was thoroughly investigated by McClintic on guinea-pigs, and by ourselves on pigs and human patients. We discarded the drug as being not only worthless in the treatment of spotted fever, but harmful.

Salvarsan was used in two human cases, the first during the spring of 1911. This patient was moribund when the drug was administered, and death followed very soon, making it impossible to draw any conclusion. It was repeated in May, 1912, in a human case about the seventh day of the disease. In both cases it was administered intravenously. Within one hour after the drug was given in the latter case the patient was in a perceptibly worse condition, became delirious, pulse rate increased, temperature rose, jaundice appeared, and a great diminution in the amount of urine followed. Within twelve hours the patient was deeply jaundiced, pulse 120, temperature 103.5°, eruption more profuse on the legs, forearms, back, also confluent in large blotches of deep blue color on dependent portions; leucocytes 10,000; spleen enlarged to one-half the distance from the ilium; blood picture as seen in the history of Harry Van H. following. The conditions rapidly became worse, and death followed within twenty-four hours after the administration of the salvarsan. It was quite evident that salvarsan was harmful in this case, and we strongly advise against its use in spotted fever. It was apparent that there were contra-indications to its use, namely, nephritis, myocarditis, and brain symptoms, but at that time sodium cacodylate—also an arsenical preparation—was being reported on favorably.

A quiet room with subdued light and an ice cap to the head for cerebral symptoms are comforting

to the patient; intermittent hot applications to the painful joints, with as little movement as possible, also give the patient some relief. One should guard against the patient getting out of bed on account of the extra strain on the heart, and start cardiac stimulants when the pulse goes over 95 in an adult. Digitalis is good, but slow in action. If strychnine is used, it should be given at short enough intervals to maintain the stimulation, and not allow a reaction to set in; about one-thirteenth of a grain should be administered every five or six hours. The urine should be measured and the amount kept to at least thirty ounces in twenty-four hours, this being the main avenue of excretion in spotted fever. The mouth should be cleansed frequently, and the use of the bed pan should be insisted upon. Of all drugs used by us, or seen used, sodium citrate gave the most promising results. Unfortunately, we did not commence using it until past the season and were unable to try the drug on human cases, but it was tried on guinea-pigs and rabbits, until the investigation was interrupted by army maneuvers. Several animals were so treated, guinea-pigs subcutaneously, rabbits subcutaneously and intravenously. The effect was very noticeable, the temperature dropped, the attack was shortened, and there was a marked general improvement noticeable in the animal. On several occasions, where the animal would set back in a corner, fur roughed, eating nothing, and very sick looking, it would make a marked improvement within twenty-four hours following this treatment. In seven animals so treated, none died, while the mortality in untreated animals, using the same strain, had been about eighty per cent. In another case, five per cent. sodium citrate solution was mixed with virulent blood and allowed to stand twelve hours at room temperature, then injected subcutaneously into a normal guinea-pig; this did not prevent the disease, but it ran a mild course, while the control animal died. (See experiment, pig No. 44-C.)

Pig No. 56-C was inoculated subcutaneously September 23 with one c.c. of virulent defibrinated spotted fever blood and immediately thereafter five c.c. of two per cent. sodium citrate solution was administered; on September 29, four c.c. of three per cent. of the sodium citrate; September 30, five c.c. of three per cent.; October 1, four c.c. three per cent.; October 2, five c.c. three per cent.; October 3, five c.c. three per cent.; October 4, seven and one-half c.c. three per cent., to see if this would prevent the attack. The animal developed spotted fever, but the disease ran a milder course than in the control, which died.

We can offer no explanation at this time for the beneficial effects indicated by this limited number of experiments, but we feel justified in recommending that the administration of sodium citrate be pushed from the first to the limit of tolerance in

man, and that the drug be given intravenously. We recommend this on the ground that it has offered promising results in a limited number of cases among lower animals so treated, that it is harmless when properly used, and that there is no other drug known that offers the slightest encouragement. It is safe to give sixty c.c. of a five per cent. sterile and freshly prepared solution intravenously. This dose can be given twice daily. Even larger doses may be administered in very grave cases. Intravenous medication is safe and simple, and the citrate can be given with a syringe or any apparatus for intravenous medication. The introduction of a small amount of air is of no importance.

Prophylaxis.—The only means of transmission now known is through the bite of an infected tick, and this is the way man becomes infected. The tick is a slow feeder, and Moore says that from one and one-half to ten hours are required for the tick to attach itself; it crawls around a great deal before becoming attached; therefore, if persons in tick-infested zones would carefully search their bodies for these pests in the morning after rising, at noon-time, and before going to bed, the chances of contracting spotted fever would be very limited. When the tick is found, remove it at once; if the head is embedded, place a drop of carbolic acid on the head and pull out the mouth part. If this breaks off, remove it with a penknife, then inject a drop of one-half official strength of iodine (3½ per cent.) into the wound. The great difficulty is that most of the cases of spotted fever occur in persons who sleep in their day clothing, and in such cases the tick is not found possibly for days after its attachment. We find that an ointment composed of spirit of turpentine, one drachm; bichloride of mercury, one grain; sulphur, one drachm; lanolin, one ounce, when rubbed into the skin of man or guinea-pig will apparently prevent the tick from attaching. This too could be used by persons going into thick infested zones during the tick season.

Prognosis.—The death rate in the Bitter Root Valley is about ninety per cent. in persons twenty-five years of age or over; it is lower in younger people, thus varying directly with the age. It is said to be about three per cent. in Idaho. The vast majority of patients, as was also the case with guinea-pigs in our experience, die on or before the ninth day. If life can be sustained until the fourteenth day, recovery is quite certain with the Bitter Root strain. The danger signs are, jaundice, pulse over one hundred (in adults), leucocytes over 10,000, absence of eosinophiles, deviation of the Arneth Index to the left, marked diminution of urine, and profuse and confluent eruption. We believe that a short incubation period forecasts a bad prognosis. We are further inclined to believe that patients infected with the Bitter Root strain and

showing the above syndrome never recover. After a case of spotted fever is diagnosed, each of the above signs is a fair index as to the patient's condition, and taken collectively they furnish the most reliable basis for the prognosis from day to day.

Complications.—Nephritis is probably present in all cases; myocardial degeneration and pneumonia occasionally occur. From the brain symptoms it would appear that meningeal irritation is present in all cases, although the postmortem fails to reveal any changes in the brain. Gangrene of the scrotum, testicle, prepuce, and faucial pillars sometimes occurs, more commonly in Idaho. Of late, paralyses have been reported following tick bites,* but we have seen no paralyses attributable to this cause.

Epidemiology.—The keynote to this phase of spotted fever cannot be struck with certainty until after the cause of the disease has been determined, some exterminable chronic source discovered, or some practical means of tick eradication arrived at. The disease is confined to small and scattered areas; where it first appeared and what caused this dissemination cannot be ascertained. Whether it actually exists in some of the localities claimed, may be doubted, as in some cases there is no experimental evidence to support the assertions, and the diagnosis of spotted fever is open to question where the eruption is not marked and no laboratory proof is at hand. A typical case can easily be diagnosed clinically. It may be possible that spotted fever first appeared in Idaho and spread to the Bitter Root Valley through Lo Lo Canyon, a pass in the Bitter Root range, and to other sections by the run of wild animals, or the shipment of domestic stock, these animals carrying with them the infected ticks. Idaho furnishes by far the largest number of cases, and the disease may have existed there longer. This, however, does not satisfactorily explain the great differences in virulence between the Idaho and Montana strains. Much work has been done in search for a chronic source from which the tick receives the virus, but with disappointing results. Ricketts and McClintic added greatly to our knowledge along this line. Both found infected ticks on wild animals, found certain wild animals susceptible and others resistant to infection by the infected *Dermacentor*; but neither found an animal that actually harbored the virus.

The fever season corresponds to the tick season, both commencing about March or April, and ending about June or July. Seed ticks are found generally on small mammals, while adult ticks are found on the large ones, including domestic animals. Ticks are much more abundant in underbrush, woodland, and in untilled fields. Cleared and cultivated fields are comparatively free. Therefore, the clearing, burning, and cultivation of these infested zones has been recommended as a means of tick eradication. The fact that spotted fever exists in sparsely settled localities makes the tilling of such fields a tremendous proposition. Burning is not practical because the combustible material is either wet from the melted snows or the rain, or is green at the time when burning would do the most good. At the time when burning would be feasible, fire would endanger the national forests and cause great economic losses. Dipping of domestic animals in specially

constructed vats filled with an arsenical parasiticide was carried out by McClintic in 1912, near Victor, Montana, with good temporary local effects. All of these means have serious drawbacks, but may be used locally to reduce, as far as possible, the number of infections, until some more thorough and practical method is discovered. Spotted fever will not be eradicated by the means referred to, but to save a single human life they are worthy of consideration. Frick's experiments with grazing sheep, showing that ninety per cent. of ticks die after getting on sheep, are encouraging and well worth serious thought. It is hoped that local ranchmen will co-operate in bringing this promising test to a satisfactory conclusion. As ticks are found on sheep, cattle, horses, wood, hay, etc., shipment of animals from infected zones may cause spotted fever to become a serious menace to public health in other localities. The tick *Dermacentor* drops from its host to molt or deposit eggs, and this may be done en route to other localities or at the destination. Many deaths occur annually in the Rocky Mountain States from spotted fever, and great depreciation in the value of land is caused by its presence. These facts, joined with the liability of other areas becoming infected, suggest a grave situation. Spotted fever should be included with the "reported diseases," in all States where it occurs; more experimental work should be done in certain States, now reporting it, to establish its presence without question, and stringent methods should be instituted to prevent its spread into uninfected localities.

The flea, bedbug, and louse are not believed to play any part in the transmission of spotted fever. One does not hear of more than one case in the same house during a season; besides these insects may be found the year round; furthermore, spotted fever is a disease of the country and not of cities. It is not known in jails and prisons where these pests are most common. Neither is the mosquito believed to play any part in the transmission. There are said to be nine species of mosquitos in the Bitter Root Valley, but after examining several hundred we found but one genus, the *culex*. Eighteen of these were placed in a specially constructed cage with an infected guinea-pig and a normal pig. Both pigs had one-half of their backs shaved so as to afford better exposure for the mosquitos. These insects were frequently seen attached to the animals; two days later the infected pig died and was removed. The normal pig was kept in this cage for two weeks; at the end of this time all the mosquitos were dead. The pig was removed and kept under observation for two weeks longer, but at no time was there any evidence of disease. On immunity test the pig developed a typical case of spotted fever. Of course, one experiment proves nothing, but it is at least significant of the unimportance of the *culex* mosquito in relation to this disease.

There remain two important epidemiological factors worthy of special mention, namely, education of the people and tick hunting. Inhabitants of infected districts should be taught the means of transmission by the tick and taught to discredit all other means, such as "swamp water," "rotting wood," "melted snow," "miasms," and other similar things. Many people in the Bitter Root Valley utterly disclaim any relationship between the tick and spotted fever. As an example, Mr. L., a large ranch owner in Lo Lo Canyon, denies the tick transmission, although he has had one or more cases on his ranch

*According to Hadeven, the tick *Dermacentor venustus*, as it occurs in the dry district of British Columbia, gives rise to a peculiar form of paralysis in sheep which, directly or indirectly, may prove fatal. Nuttall, working in Cambridge, England, substantiates Hadeven's work. The disease is non-febrile.

every year, and has lost one child from the disease. The financial loss due to the depreciation resulting from the acknowledgment of tick relationship is believed to be responsible for this disbelief.

Tick Hunting.—The tick is a slow feeder, requiring hours to attach and infect an animal. Should one regularly search the entire body for ticks at least three times a day, after being exposed, there would be very few cases of spotted fever.

We wish to express our appreciation to the Surgeon General, the Chief Surgeon of the Western Department, U. S. Army, to the Surgeon at Fort Missoula, Montana, the Director, Hygienic Laboratory, United States Public Health Service, and to the local practitioners of the Bitter Root Valley, for valuable assistance rendered during this investigation. If possible, this investigation will be continued at a future date.

the costal margin; lymph glands not enlarged; urine highly colored and albuminous; patient constipated; heart normal. Cyanotic appearance around the mouth, tongue dry, coated, and the motility sluggish; reflexes slightly increased, leucocytes 9,000; hemoglobin 100 per cent. Two guinea-pigs were inoculated intraperitoneally with 2 c.c. of blood taken from the patient, slides and cultures were also made. Patient remained in an apathetic and delirious condition for three weeks, with temperature pulse, and respirations as shown on the accompanying chart. The eruption developed typically on the 19th of April. Treatment consisted of rest in bed, liquid diet, use of the bed-pan, large amount of water by mouth, tepid sponge for temperature over 102.5°, ice cap, frequent mouth wash, quinine through the entire course, purgatives, sodium cacodylate, 1 c.c. hypodermically four times a day, from April 8 to 10, and one half c.c. to the 14th. The pigs inoculated developed typical lesions of spotted fever, and the strain was carried on for several transfers. This patient's mental condition remained very sluggish for six weeks, and his temperature occasionally went above 99° F. during this period.

CASE I.—Albert M.

CASE I.—(The only patient in the Bitter Root Valley who recovered in 1912.) Albert M., male, aged sixteen years; living on ranch west of Hamilton, Mont., in a heavily infected district. Has had measles and mumps, no other diseases of childhood. Mother and father living; family history negative for tuberculosis, malignancy, and spotted fever, although other cases of the latter disease have occurred in the neighborhood yearly. Was frequently bitten by ticks, but presumably bitten by an infected tick, March 31, 1912, back of the right ear; this area became painful and inflamed, and of a cyanotic color on the second day. Had a chill and was put to bed, April 4, 1912. On the same day an indistinct macular eruption was noticed on the ankles, wrists, forearms, and palms. The patient grew worse and was taken to the hospital, April 7, in a delirious condition. Examination at that time showed the tick bite very distinctly, and the eruption to be more marked. Temperature, 103.6°, pulse, 86, respirations, 22. The spleen was enlarged, and the liver could be felt below

CASE II.—(A typical fatal case.) Harry van H., male, aged 24 years; born in Missouri; by occupation a laborer; came West a few months ago. For the last month has been working on Mr. L.'s ranch in Lo Lo Canyon. When first seen was apathetic, and little or no personal or family history could be obtained. Friends said that he complained of tick bites about a week ago, and that he has been sick and feverish for several days. Admitted to the Post Hospital, Fort Missoula, Montana, May 6, 1912. All his clothing was carefully removed and placed in lysol solution to kill any ticks that might be contained in them. The body was then carefully examined, and no ticks found attached. Patient's expression was drawn, and eyelids heavy; articulation thick, speech very difficult to understand. On examining the skin, no changes could be found on the scalp, small bluish areas, the size of a pin's head, could be seen on the flexor surfaces of the ankles, not raised nor disappearing on pressure. A macular eruption was also discerned on both extensor

and flexor surfaces of the forearms, and over the entire back, and the soles of the feet and palms showed a deep-seated macular eruption. There was no eruption on the face, neck, thighs, or arms. The calves, chest, and abdomen showed scattered lesions. One inch below the navel a dark colored, raised papule, surrounded by an inflammatory zone appeared; this the patient claimed to be the site of the tick bite. There was no enlargement of superficial lymph glands. No evidence of venereal disease. The conjunctivæ were injected, and pharyngitis was present. Joints slightly painful, but no inflammation or swelling noticeable. Temperature 101.8°, pulse 88, respirations 26. Heart and lungs normal. Abdomen tympanitic; spleen enlarged; liver and testicles showed no change. The lips and ears were somewhat cyanotic. Breath foul, patient breathing through the mouth. Pupils equal, dilated, and reacting normally. Urine albuminous; leucocytes 11,800, differential count showed reduction in the polymorphonuclears, and an increase in large mononuclears. The peripheral circulation was poor, pulse low in ten-

CASE II. HELEY VILLI H

sion. Blood darker than normal its coagulation time increased.

A brisk purge was administered, and 20 grains of sodium acetate given t.i.d. May 8 0.34 gram of salvarsan was given intravenously, which was followed by a rapid decline in the patient's condition. Ice cap, liquids, sponge baths, and the usual general nursing.

The mental symptoms grew rapidly worse, eruption became more profuse and confluent, pulse increased, and temperature rose; urine decreased in amount, ending in suppression after temporary incontinence; spleen greatly enlarged; jaundice appeared soon after the salvarsan was given, and became marked and general by May 9. On this date there was cyanosis about the neck, ankles, wrists, lips, and ears. Muttering delirium with carphologia and subsultus, a pulse of 120, temperature 103.6°, marked jaundice, absence of eosinophiles, suppression of urine, and respiration rate of 40 showed very clearly that the end was near. The patient died the same day.

Postmortem examination showed some emaciation, rigor mortis incomplete, skin a saffron hue, the eruption showing distinctly on the arms, forearms, wrists, palms, legs, soles, back and chest. The fluidity of the blood and its extremely dark color were very noticeable on incising the skin. The lungs were sunken into the back of the thoracic cavity, anthracosed; no evidence of adhesions or recent inflammation. Right heart engorged and contained clots. Abdominal viscera showed signs of jaundice, more marked in the great omentum. Stomach and intestines filled with gas, no inflammation. Spleen greatly enlarged, dark, firm, indented in several places, hemorrhagic, and bleeding freely on section. Pancreas yellow and acutely congested. Liver enlarged, subcapsular hemorrhage, twice the size of a silver dollar, on the right lobe. Gall bladder partially filled with dark bile. Kidneys engorged, and on section showed small hemorrhages in the cortex. Adrenals yellow and acutely congested. Testicles adherent to the scrotum, and presenting gangrenous changes. The cerebrospinal system was not examined. Diagnosis: Rocky Mountain spotted (tick) fever.

THE CRAVING FOR THE SUPERNATURAL.*

By TOM A. WILLIAMS, M.B., C.M. (EDIN.),

WASHINGTON, D. C.

LECTURER ON NERVOUS AND MENTAL DISEASES, HOWARD UNIVERSITY, NEUROLOGIST TO EPIPHANY DISPENSARY AND FREED-
SEN'S HOSPITAL, CHICAGO; MEMBER, NEUROLOGICAL AND PHYSIOLOGICAL SOCIETIES OF PARIS, ETC.

The Nature of Craving.—Craving is a sign of physiological need. It is a sensory phenomenon, of which, however, explicit awareness cannot always be discovered. It is conspicuously noticed in cases of disturbance of the body secretions, such as occurs in over-function of the thyroid gland. It is regarded as a crude body-consciousness that something is the matter. In motor organisms it causes visible reaction: this expresses itself in what is termed restlessness. But the unrest may show itself by a fixation, more particularly in the muscles of emotional expression, although the manifestation is not confined to these; shallow respirations and restricted amplitude of movement in limbs and trunk may be observed also. In cerebrate animals the reaction of the individual is under the guidance of preceding impressions stored in the pallium and known as memories; whereas in the animals without a pallium the reaction is accomplished through stable mechanisms known as instincts. Both of these types of reactions are tropisms merely; but the former are liable, conditionable; whereas the latter cannot be modified. The science of conditionable reactions of cerebrate animals is called psychology; and the means by which the reactions are influenced are called psychogenetic, whether these are healthy or diseased. It must not be forgotten, however, that the genesis of a psychological disturbance may be purely somatic, although the manner in which the reaction shows itself is contingent mainly upon the features of the individual which have been derived from previous sensory impressions and their resultant motor reactions commonly known as experience. It is the influence of these upon the hereditary dispositions of the individual which constitute what is known as "make up" or character; and it is this which determines the form which reaction to stimulus must take, whether the stimulus is purely psychological or somatic.

Discomfort.—Now physiological discomfort is an experience universal at one time of life or another; but the reaction to it is infinite in variety, and while part of it depends upon the congenital dispositions which are the common property of humanity, a larger part is contingent upon the psychogenetic factors which have stamped the individual.

The Supernatural.—Now an influence which has been of great significance to every human being since the traditional period, at least, has been the concept of the universe regnant at the period of that individual's life. The insistence by its protagonists upon this concept as the ultimate motive of human endeavor made its acceptance almost universal at periods when it was the custom to lean upon the dicta of authority for guidance in life,

*Address delivered before the Southern Society for Philosophy and Psychology at their Tenth Annual Meeting, in affiliation with the American Psychological Association and the American Association for the Advancement of Science, December, 1914, at Philadelphia, Pa.

even when blind obedience was not the rule. Now in natural affairs inconvenient questionings and scepticisms towards dogmatisms would ultimately reach truth. But inaccessibility to verification of what was called supernatural, made authority, rather than investigation, its criterion: excommunication from the tribe would still all criticism. Thus every act of life became permeated by motives originated in arbitrary interpretations of a supernature.

These influences were specially conspicuous concerning the difficulties of man's almost blind struggle against the uncomprehended astronomical and geodetic phenomena marveled at and fled from, as well as the pestilences which ravaged him. In his sociological affairs, too, every act or thought became imbued with a relationship to an extraneous power.

It is by these social and physical phenomena that the greatest appeal is made to the states of feeling termed emotions and sentiments. So that it became the custom to invoke concerning ill states of feeling the reference to a supernatural influence. Thus, from the cradle up, the ordering of social relationships was made dependent upon the simple expedient of the supernatural extraneous agent rather than upon the more difficult and elaborate analysis and synthesis which would have been required for a proper investigation of each perturbing circumstance in its relation to life as a whole. The power of this influence was inversely proportional to the resiliency and tenacity as well as the general well-being of the individual.

But not only is reference to the supernatural favored by traditional cosmogony, but because of certain psychological features of the individual himself there is a tendency towards supernatural explanations of the introspective observations. The occasions of introspection of this kind are two, and I am not speaking of the inculcated introspection of the moralists. One of these occasions is the self-examination into his conduct which is a normal character of a thinking being. This will often give rise to supernatural explanations even when the introspection is not determined by the tradition of which I have already spoken.

The second kind of occasion demanding introspection, is the autochthonous emanation of feeling of unaccustomed character. Such feelings occur at the physiological epochs; but at these times they are readily explained in a familiar and simple way, and hence no supernatural agency is usually invoked. A similar explanation is made readily enough in cases of evident bodily disease, even where mental symptoms are prominent, for it is no longer the custom to speak of demon possession even in the acute deliria. But even where no physiological epoch or clearly defined physical disease stands forth, unusual feelings are no uncommon phenomenon; and they demand explanation. Such occur conspicuously in the psychopathological syndrome so completely described by Janet under the term *psychasthenia*. Persons thus afflicted, feeling an incapacity and an impediment to their free activity and not recognizing that they are sick, endeavor to interpret their feelings. Of course, the interpretation varies somewhat in accordance with the nature of the feelings, and with the person's information about the world and his psyche. But quite apart from modifications of this type, I have found it very common for patients to declare, "I feel as if there was another person in me," or, "I feel compelled as if by another agency to act thus." The explanation of a super-

natural agent weighing upon them becomes very easy. For the purposes of this discussion, it is not important whether *psychasthenia* arises purely from degeneration of structure, or from faults in the chemistry of the plasma which bathes the nerve structures, or whether it is a purely psychopathological condition to which the physical phenomena are secondary, as some would have us believe. Our object is merely the setting forth of the fact that it is a diseased condition which disposes its victim towards metaphysical explanations.

Mystical States.—As the religious experience is at bottom a peculiar feeling or sentiment, one has a right to inquire into the nature of this. It is in reality constituted by very common elementary feelings. One set belonging to the class which includes fright, horror, apprehension, veneration and respect; another set is the class of the tender emotions, admiration, love, and finally ecstasy. The excess of religious fervor, moreover, accompanies many alienated states quite different from one another; for it may occur in the agonizing horrors of depressed states (a mystical delirium), as well as in the expansive pride of excited psychoses, where the delusion may precede to the point of Godhood.

Of course, as the religious feeling was one of the earliest and most important of the facts of social life, its germ, present in most people, can very often be found in any ruin of the intelligence and feelings. Besides, theological doctrines even in our own day pervade instruction from the cradle to the university; and it would be strange if the powerful social constraints and suggestions of formal religion did not modify the reactions of an unstable mind just as they influence the mental content of us all. These effects of religious doctrine, however, differ from the "sentiment," in which the *feeling* of the mysterious, the union with divinity, dominates the person to the exclusion of all mundane considerations and plunges him or her into contemplative ecstasies which may reach the extent of union with divinity, the apotheosis of mysticism.

Mysticism, then is the *sentiment* of which religiosity is the intellectual counterpart. It is the *feeling* accompanying the belief in an unknown, mysterious, incomprehensible power—a supernature. Mere intellectual acquiescence in a doctrine of this kind does not make one a mystic, for the latter is ruled by warm feeling and not by cold judgment.

Mysticism is, however, the common basis of faith, whether in religion, spiritualism or in magic and sorcery. It is this peculiar feeling which gives men the idea that the facts to which it is attached possess a "value" all their own which takes them from the profane to the sacred realm, before which the criteria of normal life fall into abeyance.

The desire to achieve this feeling, which in essence is closely allied to those of sexual origin, may lead to religious fervor proper, shown in "works"; but it is just as likely to remain a mere passive beatitude satisfied with its own inner experiences and wrapped up in these. It is an all sufficient orgasm the companion of which is an imaginary being who satisfies better than flesh and blood.

Psychasthenic Manias, or Besetments.—The religious monomanias, to use an obsolete term, arise quite differently. In them the patient is obsessed by an idea or a doubt derived purely from his intellectual environment. The distress he feels is due to the state of doubt as to the validity of his idea, he has no real religious feeling but a mere intellectual dissatisfaction, and is not therefore a

mystic. Even when he appears filled with enthusiasm, this is suggested to him from without; it is not a part of his being; he is a false mystic, not in the sense of being a pharisee, but because he unconsciously affects a sentiment which he does his best to imitate. It is as unnatural to him as is bipedal progression to a dog.

The Deluded.—Many insane with delusions of persecution pass through a short phase of mysticism in that they suppose that "intangible" enemies with "inconceivable" powers act upon them in a manner which "ordinary people cannot divine," and which the patient can only defend himself against by some "marvelous" invention of the imagination. This requires "special virtues," faculties acting in supernatural ways. The meeting of several individuals in this state of mind very easily furnishes a circle of spiritualism, sorcery, or some branch of the occult.

The religious turn of a mystic's thoughts is an accident of environment just as much as in the case of the monomaniacs. A most striking example of this is the case of a young French girl whose mother became insane because of the patient's father's and brother's deaths, the latter of which she refused to believe on account of frequent hallucinatory interviews. After this misfortune, the young woman began to "feel quite different"; following which she had "moral communion" with evil powers. Eventually nothing could be done without the intervention of these, from whom she hoped to recover her lost fortunes, health, and family.

Now, this young woman scorned religious beliefs and practices, knew nothing of spiritualism, disbelieved in fortune telling; but as do savages, showed reluctance to speak of the mysterious powers around her, whom she believed to have deceived her about her brother's death; that is to say, her mystical conceptions prevailed over her actual experience.

*The Cause of Superstitious Feeling.**—The change in the feeling of personality is the foundation of this girl's disorder, and the same cause can be traced for all the cases. It arises in the first place from physical disorder, such as the poisoning of the brain cells by a chronic infection, such as the fever contracted in child-bearing, alimentary or other intoxications, the perversion of the secretions by psychical means, like prolonged grief or worry, in all of which diminished oxidation plays a large part. The brain function thus perturbed, no clear recognition of men and things occurs, only a vague ideation is possible. Hence, the sentiment of unusualness, mystery, supernatural, the primitive mystical feeling. The impression is so powerful that the patient can easily negate the former and present experiences of his senses, and from the exceptional character of the "experience" he deduces a supernatural quality of the "force" which "must have caused it." The qualities he attributes to the power depend upon the stock of ideas he has possessed. A believer will say "in order to have so much power over everything it can only be the Holy Ghost." On the contrary, a patient who held no strong belief before her alienation, merely complained of the feeling that her intelligence had gone, that she was no longer herself, although her body remained the

same. Another had the feeling that she was in a dead world, and therefore must herself be dead. "It is black all around, there is no world there; but you cannot understand and I cannot explain it." And yet this woman retained her perceptive intellectual faculties undiminished.

Perturbations of the internal feelings of physical causation are then at the root of mysticism, and this is shown most clearly by their appearance or recrudescence at the epochs of puberty, menstruation, and the climacteric. The practical application of these facts is well known in the rites and ceremonies imposed in heathen ritual.

It is only when the system is unbalanced that the mystical experience can be felt. And it is not easy for a modern, unless he has studied defectives, to conceive the illogical mind of the primitive savage. It is hard for a sane mind to achieve religious exaltation; and it can never arrive at the true mystical feeling. It is a sort of uneasiness which prevents comfort in the feelings of certainty, in the operations of the intellect and decision of action. The patient finding himself aboulie and perhaps too critical minded to accept the mundane supports in his vicinity, seeks a solace in that which to him seems powerful because incomprehensible; that is to say something supernatural.

For this it is not essential that the victim's mind be pervaded by the infantine cosmogony which parades often as religious truth. Without anything of the sort, there may arise naive interpretations, hardly even having explicit reference to supernatural agents. For example, a patient may say, "If I begin on Friday, a certain undertaking will fail." "If I do not turn my vest twice, misfortune will occur." "It is incumbent upon me to turn round in my chair, or the negotiations will fail." The enumeration of expedients would be endless. The above are from three different patients, one a boy of 14 now completely cured; the second from the son of a very prominent public man now quite restored to health; the third from a case now quite recovered. In none of these, save the last, was the bodily state of importance: the psychological reactions were the sole object of therapeutic effort, and their ordination was accomplished by purely psychological means.

1705 N STREET

SUNLIGHT A NECESSITY FOR THE MAINTENANCE OF HEALTH.

BY J. W. KIME, M.D.

SORT DOG, N. JOWA

SUPERINTENDENT FOLDER LODGE SANATORIUM

THERE are few lessons so difficult to learn as the lesson of sunlight. The chapter on fresh air is beginning to be understood—only beginning, however, for thousands of windows still are tightly closed both day and night which should be widely opened for the admission of the fresh pure air from without. But that light, sunlight, is of the greatest value in the maintenance of health, and even of life, is comprehended by but few, indeed by almost none at all. Even physicians do not know, or, knowing, fail to heed the necessity for the admission of sunlight to their homes.

In consequence we find in every city and in every rural district splendid homes which are swamped in trees—swamped to such an extent that even the grass refuses to grow; the windows are small

*This is not necessarily the cause of superstitious belief; for this is often inculcated or derived from collective suggestion as in the naive minded who pursue faith healing cults.

and few in number, and even upon these, the shades are pulled far down to exclude the light. These homes are dark and often are damp—the very conditions most favorable to bacterial growth. In homes like these ill health must be the rule.

In the plant world light is essential for health and growth. If grown within the house, the shoots are weak and pale and spindling while just without, where the sunshine falls, the same plants are strong and rugged and clothed in green.

In dark places, in caves and cellars where but few straggling rays of light may enter, plant life is devoid of health and strength and color. The energy imparted by sunlight is wholly lacking; the rich green chlorophyl which only the sunlight paints in grass and leaf and flower is not imparted in caves and gloomy places where sunlight never falls.

The familiar and homely potato proclaims an eloquent lesson of the beneficent powers of sunlight. We store this vegetable in places that are dark and close; a dingy window in the basement wall admits a fraction of light. Along toward spring-time the "eyes" begin to swell and soon long, white, fragile sprouts emerge and creep long distances upon the dark cold floor. These "sprouts" are identical with the tough green stalks in the open garden upon whose rootlets these useful tubers grow.

In plant life sunlight measures the distance between life and death.

The human type confined indoors is pale and weak and bloodless. If blood there be it is but tinged with red; the deep red colors which only the sunlight paints are reserved for those who live outdoors.

It therefore comes about in the course of time, and of human events, that every fourth generation we must go back to the rural dwellers for a new influx into urban life. Indeed, were it not for this steady stream continuously flowing from rural to urban districts, our city life would soon lose much of its virile power.

City life is life within doors—in shop and factory, in office and counting room, in homes, too often, from which sunlight is removed; it is life in which the blood runs pale. It is close akin to the life which creeps and crawls on the dark damp floor beneath the house.

There once was a race of human dwellers that lived in caves. They burrowed beneath the ground, they scaled great cliffs and dug into their walls. From out their homes the light of day was wholly shut—and of the cliff dwellers only these caverns now remain.

The dwellers in cities, and too often those in the country, approach in a measure, in their habitations, the darkened homes of these forgotten peoples. Their homes are dark, the sunlight is excluded, the houses are swamped in trees. The conditions are those too nearly related to life within the cave.

Light is an energy of wondrous power. Great trees bend and grow toward it. Light paints the color of every flower and tinges the cheek with the glow of health. Without light, the world would be dead and the firmament be blotted out. In darkness, it is not possible for man to live. Reason fails, the health breaks, and death soon comes.

De Laroquette has observed that "the human body, like the plant, draws from the sun an important part of the energy necessary for the main-
